U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES
Public Health Service
National Institutes of Health

#### **FOREWORD**

The National Toxicology Program (NTP) is made up of four charter agencies of the U.S. Department of Health and Human Services (DHHS): the National Cancer Institute (NCI), National Institutes of Health; the National Institute of Environmental Health Sciences (NIEHS), National Institutes of Health; the National Center for Toxicological Research (NCTR), Food and Drug Administration; and the National Institute for Occupational Safety and Health (NIOSH), Centers for Disease Control and Prevention. In July 1981, the Carcinogenesis Bioassay Testing Program, NCI, was transferred to the NIEHS. The NTP coordinates the relevant programs, staff, and resources from these Public Health Service agencies relating to basic and applied research and to biological assay development and validation.

The NTP develops, evaluates, and disseminates scientific information about potentially toxic and hazardous chemicals. This knowledge is used for protecting the health of the American people and for the primary prevention of disease.

The studies described in this Technical Report were performed under the direction of the NIEHS and were conducted in compliance with NTP laboratory health and safety requirements and must meet or exceed all applicable federal, state, and local health and safety regulations. Animal care and use were in accordance with the Public Health Service Policy on Humane Care and Use of Animals. The prechronic and chronic studies were conducted in compliance with Food and Drug Administration (FDA) Good Laboratory Practice Regulations, and all aspects of the chronic studies were subjected to retrospective quality assurance audits before being presented for public review.

These studies are designed and conducted to characterize and evaluate the toxicologic potential, including carcinogenic activity, of selected chemicals in laboratory animals (usually two species, rats and mice). Chemicals selected for NTP toxicology and carcinogenesis studies are chosen primarily on the bases of human exposure, level of production, and chemical structure. The interpretive conclusions presented in this Technical Report are based only on the results of these NTP studies. Extrapolation of these results to other species and quantitative risk analyses for humans require wider analyses beyond the purview of these studies. Selection *per se* is not an indicator of a chemical's carcinogenic potential.

Details about ongoing and completed NTP studies, abstracts of all NTP Technical Reports, and full versions of the completed reports are available at the NTP's World Wide Web site: http://ntp.niehs.nih.gov. In addition, printed copies of these reports are available from the NTP as supplies last by contacting (919) 541-1371.

# **ABSTRACT**

#### Diisopropylcarbodiimide

CAS No. 693-13-0

Chemical Formula: C<sub>7</sub>H<sub>14</sub>N<sub>2</sub> Molecular Weight: 126.20

**Synonyms:** 1,3-Diisopropylcarodiimide; N,N'-diisopropylcarbodiimide; N,N'-methanetetraylbis (2-propanamine)

Diisopropylcarbodiimide is used as a reagent for peptide syntheses and as a chemical intermediate. The National Cancer Institute nominated diisopropylcarbodiimide for study as a representative chemical in the alkylcarbodiimide class because of its acute toxicity, its use in chemical, pharmaceutical, and recombinant DNA industries, and the absence of data on potential health effects. Male and female F344/N rats and B6C3F<sub>1</sub> mice were administered diisopropylcarbodiimide (greater than 99% pure) dermally for 2 weeks, 3 months, or 2 years. Genetic toxicology studies were conducted in *Salmonella typhimurium*, rat and mouse bone marrow cells, and mouse peripheral blood erythrocytes.

#### 2-WEEK STUDY IN RATS

Groups of five male and five female F344/N rats were dermally administered 0.3 mL ethanol containing 0, 3, 9, 27, or 81 mg diisopropylcarbodiimide or 0.3 mL of the neat chemical containing 242 mg per animal, 5 days a week for 2 weeks. All rats in the 27, 81, and 242 mg groups died before the end of the study. Of the surviving groups, final body weights were similar to those of the vehicle controls. Clinical findings included convulsions/seizures,

nasal/eye discharge, tremors, and comatose conditions in 81 and 242 mg rats and lethargy, ataxia, and abnormal breathing in 27 mg rats. The incidences of epidermal hyperplasia at the site of application in 9 and 27 mg males and 27 mg females were significantly greater than those in the vehicle controls; the incidences of hyperkeratosis in 3 and 9 mg males and 9 mg females were also significantly increased.

#### 2-WEEK STUDY IN MICE

Groups of five male and five female B6C3F<sub>1</sub> mice were dermally administered 0.1 mL ethanol containing 0, 1, 3, 9, or 27 mg diisopropylcarbodiimide or 0.1 mL of the neat chemical containing 81 mg per animal, 5 days a week for 2 weeks. All 9, 27, and 81 mg males and females died before the end of the study. Final body weights of the surviving groups were similar to those of the vehicle controls. Clinical findings in 9, 27, and 81 mg males and females included comatose conditions, convulsions/seizures, tremors, abnormal breathing, nasal/eye discharge, lethargy, and irritation at the site of application. Incidences of chronic active inflammation at the site of application in 9 mg males and females were significantly greater than those in the vehicle control groups.

#### 3-MONTH STUDY IN RATS

Groups of 10 male and 10 female core study F344/N rats were dermally administered 0, 10, 20, 40, 80, or 160 mg diisopropylcarbodiimide/kg body weight in ethanol, 5 days per week for 3 months. Groups of 10 male and 10 female clinical pathology rats were administered the same doses for 22 days. All 160 mg/kg male and female core study rats were sacrificed moribund or died within the first week of the study. All 80 mg/kg males and females died or were found moribund by day 59. Significant decreases in body weight gain occurred in 40 mg/kg males and females, and a significant decrease in final mean body weight occurred in 40 mg/kg females. Clinical findings in groups administered 40 mg/kg or more generally included irritation of the skin at the site of application, seizures, ataxia, abnormal breathing, ruffled fur, thinness, and lethargy. Significantly increased incidences of skin lesions at the site of application included epidermal hyperplasia in all dosed groups of males (except 160 mg/kg) and 40 mg/kg or greater females, epidermal necrosis in 160 mg/kg males and females, and chronic active

inflammation in 80 and 160 mg/kg males and females. Significantly increased incidences of nonneoplastic lesions occurred in the brain, lung, and liver (males only) of males and females administered 80 or 160 mg/kg.

#### 3-MONTH STUDY IN MICE

Groups of 10 male and 10 female B6C3F<sub>1</sub> mice were dermally administered 0, 17.5, 35, 70, 140, or 280 mg/kg diisopropylcarbodiimide in ethanol, 5 days per week for 3 months. All 280 mg/kg males and females and nine 140 mg/kg males and females died before the end of the study. The final mean body weight gain of 70 mg/kg males was significantly less than that of the vehicle control group. Clinical findings observed in 140 and 280 mg/kg males and females included abnormal breathing, ataxia, comatose conditions, convulsions/seizures, irritation at the site of application, lethargy, ruffled fur, and thinness. Significant increases in kidney weights occurred in 17.5 and 35 mg/kg males. Significant decreases in total spermatid heads per testis and average spermatid count occurred in 17.5 mg/kg males. At the site of application, the incidences of epidermal hyperplasia in males and females administered 70 mg/kg or greater, chronic inflammation in 140 and 280 mg/kg males and 70 mg/kg or greater females, and sebaceous gland hyperplasia in 140 mg/kg males were significantly increased. Thymic atrophy was significantly increased in 140 and 280 mg/kg males and females.

#### 2-YEAR STUDY IN RATS

Groups of 50 male and 50 female F344/N rats were dermally administered 0, 10, 20, or 40 mg/kg diisopropylcarbodiimide in anhydrous ethanol 5 days per week for 2 years. Survival of 20 mg/kg males was significantly greater than that of the vehicle controls; survival of all dosed groups of females was similar to that of the vehicle controls. Body weights of 40 mg/kg male and female rats were generally less than those of the vehicle controls after week 13. Clinical findings frequently observed in 40 mg/kg male rats included ataxia, excitability, impaired gait, low muscle tone, abnormal breathing, lethargy, vocalization, and seizures.

Because of severe neurological signs exhibited by the 40 mg/kg males, a neuropathological review of these animals was performed. The principal pathological findings of the brain included neuronal necrosis, hemorrhage, and/or fibrinoid arteriole necrosis.

Incidences of hemorrhage in the lung of 40 mg/kg males, chronic lung inflammation in 10 and 20 mg/kg females, and alveolar epithelium hyperplasia in 20 mg/kg females were significantly greater than those of the vehicle controls. At the site of application, the incidences of epidermal hyperplasia in all dosed groups of males and 20 and 40 mg/kg females and chronic inflammation in all dosed groups of males and 40 mg/kg females were significantly increased.

#### 2-YEAR STUDY IN MICE

Groups of 50 male and 50 female B6C3F<sub>1</sub> mice were dermally administered 0, 10, 20, or 40 mg/kg diisopropylcarbodiimide in anhydrous ethanol, 5 days per week for 2 years. Survival of all dosed groups was similar to that of the vehicle control groups. Mean body weights of dosed groups of mice were generally similar to those of the vehicle control groups throughout the study. There were no increased incidences of neoplasms that were attributed to the administration of diisopropylcarbodiimide. Significantly increased incidences of epidermal hyperplasia and focal dermal inflammation of the skin at the site of application occurred in 20 mg/kg male mice.

#### **GENETIC TOXICOLOGY**

Diisopropylcarbodiimide was not mutagenic in *Salmonella typhimurium* strains TA97, TA98, TA100, or TA1535 with or without liver S9 activation enzymes. *In vivo*, the frequency of micronucleated normochromatic erythrocytes was significantly increased in male and female mice after 3 months of dermal exposure to diisopropylcarbodiimide. In addition, significantly elevated frequencies of micronucleated polychromatic erythrocytes (reticulocytes) and micronucleated normochromatic erythrocytes were seen in male mice during a 4-month dermal exposure to diisopropylcarbodiimide. Negative results were obtained, however, in an acute

three-injection rat bone marrow micronucleus study. A three-treatment acute micronucleus test with diisopropylcarbodiimide in male mice also showed no increase in micronucleated erythrocytes, but results of a single injection micronucleus test with diisopropylcarbodiimide in male mice were concluded to be equivocal, due to an increase in micronucleated erythrocytes seen in peripheral blood but not in bone marrow preparations.

#### **CONCLUSIONS**

Under the conditions of these 2-year dermal studies, there was *no evidence of carcinogenic activity\** of disopropylcarbodiimide in male or female F344/N rats or B6C3F<sub>1</sub> mice administered 10, 20, or 40 mg/kg.

Diisopropylcarbodiimide was associated with clinical signs of neurotoxicity and with brain hemorrhage in male rats.

<sup>\*</sup> Explanation of Levels of Evidence of Carcinogenic Activity is on page 13.

#### EXPLANATION OF LEVELS OF EVIDENCE OF CARCINOGENIC ACTIVITY

The National Toxicology Program describes the results of individual experiments on a chemical agent and notes the strength of the evidence for conclusions regarding each study. Negative results, in which the study animals do not have a greater incidence of neoplasia than control animals, do not necessarily mean that a chemical is not a carcinogen, inasmuch as the experiments are conducted under a limited set of conditions. Positive results demonstrate that a chemical is carcinogenic for laboratory animals under the conditions of the study and indicate that exposure to the chemical has the potential for hazard to humans. Other organizations, such as the International Agency for Research on Cancer, assign a strength of evidence for conclusions based on an examination of all available evidence, including animal studies such as those conducted by the NTP, epidemiologic studies, and estimates of exposure. Thus, the actual determination of risk to humans from chemicals found to be carcinogenic in laboratory animals requires a wider analysis that extends beyond the purview of these studies.

Five categories of evidence of carcinogenic activity are used in the Technical Report series to summarize the strength of the evidence observed in each experiment: two categories for positive results (clear evidence and some evidence); one category for uncertain findings (equivocal evidence); one category for no observable effects (no evidence); and one category for experiments that cannot be evaluated because of major flaws (inadequate study). These categories of interpretative conclusions were first adopted in June 1983 and then revised in March 1986 for use in the Technical Report series to incorporate more specifically the concept of actual weight of evidence of carcinogenic activity. For each separate experiment (male rats, female rats, male mice, female mice), one of the following five categories is selected to describe the findings. These categories refer to the strength of the experimental evidence and not to potency or mechanism.

- Clear evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing a dose-related (i) increase of malignant neoplasms, (ii) increase of a combination of malignant and benign neoplasms, or (iii) marked increase of benign neoplasms if there is an indication from this or other studies of the ability of such tumors to progress to malignancy.
- Some evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing a chemical-related increased incidence of neoplasms (malignant, benign, or combined) in which the strength of the response is less than that required for clear evidence.
- Equivocal evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing a marginal increase of neoplasms that may be chemical related.
- No evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing no chemical-related increases in malignant or benign neoplasms.
- Inadequate study of carcinogenic activity is demonstrated by studies that, because of major qualitative or quantitative limitations, cannot be interpreted as valid for showing either the presence or absence of carcinogenic activity.

For studies showing multiple chemical-related neoplastic effects that if considered individually would be assigned to different levels of evidence categories, the following convention has been adopted to convey completely the study results. In a study with clear evidence of carcinogenic activity at some tissue sites, other responses that alone might be deemed some evidence are indicated as "were also related" to chemical exposure. In studies with clear or some evidence of carcinogenic activity, other responses that alone might be termed equivocal evidence are indicated as "may have been" related to chemical exposure.

When a conclusion statement for a particular experiment is selected, consideration must be given to key factors that would extend the actual boundary of an individual category of evidence. Such consideration should allow for incorporation of scientific experience and current understanding of long-term carcinogenesis studies in laboratory animals, especially for those evaluations that may be on the borderline between two adjacent levels. These considerations should include:

- · adequacy of the experimental design and conduct;
- · occurrence of common versus uncommon neoplasia;
- progression (or lack thereof) from benign to malignant neoplasia as well as from preneoplastic to neoplastic lesions;
- some benign neoplasms have the capacity to regress but others (of the same morphologic type) progress. At present, it is impossible to identify the difference. Therefore, where progression is known to be a possibility, the most prudent course is to assume that benign neoplasms of those types have the potential to become malignant;
- · combining benign and malignant tumor incidence known or thought to represent stages of progression in the same organ or tissue;
- latency in tumor induction;
- multiplicity in site-specific neoplasia;
- · metastases;
- supporting information from proliferative lesions (hyperplasia) in the same site of neoplasia or in other experiments (same lesion in another sex or species);
- presence or absence of dose relationships;
- statistical significance of the observed tumor increase;
- · concurrent control tumor incidence as well as the historical control rate and variability for a specific neoplasm;
- survival-adjusted analyses and false positive or false negative concerns;
- · structure-activity correlations; and
- in some cases, genetic toxicology.

# NATIONAL TOXICOLOGY PROGRAM BOARD OF SCIENTIFIC COUNSELORS TECHNICAL REPORTS REVIEW SUBCOMMITTEE

The members of the Technical Reports Review Subcommittee who evaluated the draft NTP Technical Report on diisopropylcarbodiimide on September 27-28, 2005, are listed below. Subcommittee members serve as independent scientists, not as representatives of any institution, company, or governmental agency. In this capacity, subcommittee members have five major responsibilities in reviewing the NTP studies:

- · to ascertain that all relevant literature data have been adequately cited and interpreted,
- to determine if the design and conditions of the NTP studies were appropriate,
- to ensure that the Technical Report presents the experimental results and conclusions fully and clearly,
- to judge the significance of the experimental results by scientific criteria, and
- to assess the evaluation of the evidence of carcinogenic activity and other observed toxic responses.

#### SUMMARY OF TECHNICAL REPORTS REVIEW SUBCOMMITTEE COMMENTS

**Note:** A summary of the Technical Reports Review Subcommittee's remarks will appear in a future draft of this report.

# INTRODUCTION

#### Diisopropylcarbodiimide

CAS No. 693-13-0

Chemical Formula: C<sub>7</sub>H<sub>14</sub>N<sub>2</sub> Molecular Weight: 126.20

**Synonyms:** 1,3-Diisopropylcarodiimide; N,N'-diisopropylcarbodiimide; N,N'-methanetetraylbis (2-propanamine)

#### CHEMICAL AND PHYSICAL PROPERTIES

Diisopropylcarbodiimide is a colorless liquid, with a boiling point of 145° to 148° C, a flash point of 33° C (closed cup), a refractive index of 1.433, and a density of 0.806 g/mL (*Aldrich*, 1988). It is flammable; soluble in chloroform, methylene chloride, acetonitrile, dioxane, dimethylformamide, and tetrahydrofuran; and reacts with water to form 1,3-diisopropylurea. Diisopropylcarbodiimide is a member of the carbodiimide class of chemicals. Diisopropylcarbodiimide is available in purities ranging from 97% to 99% in quantities up to 1,000 kg. The main impurities are unreacted isocyanates and polymerized carbodiimides (*Janssen Chimica*, 1990; Kuney, 1990).

## PRODUCTION, USE, AND HUMAN EXPOSURE

Diisopropylcarbodiimide is manufactured primarily by four processes. In the first process, diisopropylcarbodiimide is produced by extended or excessive heating of isopropyl isocyanate from 100° to 250° C under anhydrous conditions to condense the carbodiimide with elimination of carbon dioxide. A number of

catalysts are effective in accelerating this reaction to the extent of making it a practical synthesis for this symmetrical carbodiimide. The phospholine oxides are particularly effective catalysts, although simple trialkylphosphine oxides or even triethyl phosphate may be used (Chadwick and Cleveland, 1979). Other organometallic catalysts, including tetraisopropyltitanate and tetraisopropylzirconate, are also used to produce diisopropylcarbodiimide (Budnick, 1968; Smeltz, 1969).

In a second process, N,N'-diisopropylthiourea is reacted with cyanuric chloride in dichloromethane to yield an oily product, which, when hydrolyzed with sodium hydroxide and heated, yields diisopropylcarbodiimide and trithiocyanuric acid (Furumoto, 1971a). Thirdly, diisopropylcarbodiimide can be obtained by treating N,N'-diisopropylthiourea in dichloromethane with dichlorodicyanobenzoquinone; the resultant mixture is evaporated and heated in sodium hydroxide to yield diisopropylcarbodiimide (Furumoto, 1971b).

In a fourth process patented by Celanese Corporation in 1967, a reaction mass consisting of diisopropylthiourea, lead oxide, and water is heated to refluxing temperature, the mixture is distilled, and diisopropylcarbodiimide is separated by decantation (White and Mullin, 1967).

Although carbodiimides were discovered in 1873, it was not until the early 1950s that they were used in industry. Reactivity of these compounds with free carboxyl groups made them valuable as stabilizing agents in elastomers, natural rubber, and many types of polyolefins, polyesters, resins, fibers, cellulose esters, and foam materials to protect against deterioration. In 1953, it was discovered that carbodiimides are potent condensing agents for mono- and diesters of phosphoric acid and for the corresponding di- and tetraesters of pyrophosphoric acid. Since then, these chemicals have been widely used in the synthesis of *ortho*- and pyrophosphate esters, nucleotides, cyclic phosphates, oligoribonucleotides, polynucleotides, nucleoside-5'-phosphoroamidates, and mixed anhydrides (Azzi *et al.*, 1984).

Diisopropylcarbodiimide is a key chemical in the carbodiimide class. It is a useful reagent for peptide syntheses, especially solid-phase peptide synthesis. For example, diisopropylcarbodiimide is used as a peptide coupling reagent in the synthesis of protected peptide proteins of scorpion neurotoxin II, the *N*-hydroxysuccinamide active ester of diethylenetriaminepentaacetic acid (DTPA) (which is subsequently used in a process for conjugating DTPA to proteins), *N*-acyl ureas, and 2-alkoxyoxazolones from alkoxycarbonylamino acids, and as a condensing reagent in dipeptide synthesis (Bates *et al.*, 1981; Orlowska *et al.*, 1983; Izdebski and Pelka, 1984; Kricheldorf *et al.*, 1985; Paxton *et al.*, 1985; Sabatier *et al.*, 1987). In addition, diisopropylcarbodiimide is used as a chemical intermediate in the synthesis of *N*-silylformamides (Ojima *et al.*, 1974) and in the preparation of polyimide precursor coatings for electrophoretic image display fabrication (Minnema and Van der Zande, 1988).

There are numerous other proposed uses for diisopropylcarbodiimide. It has been reported that insoluble resinbound diisopropylcarbodiimide, in the presence of 1-hydroxybenzotriazole, catalyzed the synthesis of the cyclic peptide gramicidin S (Nutt, 1978). Also, alpha, beta-dehydroamino acid derivatives can be made from serine, threonine, or cysteine using diisopropylcarbodiimide (Miller, 1980). Diisopropylcarbodiimide has been used as a stabilization reagent for a solution of S-(diisopropylaminoethyl)-O-ethyl methylphosphonothioate (Buckles and Lewis, 1977). In organic synthesis, diisopropylcarbodiimide has been used in cycloaddition reactions to form a number of heterocyclic compounds (*Aldrich*, 1988). Like most carbodiimides, diisopropylcarbodiimide has also been used in dehydration reactions for conjugated alkadienoic acid and anhydride preparations. In the presence of (dimethylamino)pyridinium toluenesulfonate as a catalyst, diisopropylcarbodiimide has been used to prepare polyester from hydroxyphenyl-terminated carboxylic acids (Moore and Stupp, 1990). Diisopropylcarbodiimide is used as a stabilizer for the military nerve agent, sarin (Nasr *et al.*, 1988).

Potential human exposure to diisopropylcarbodiimide is based on its use as a stabilizer in sarin, the extensive handling of the compound that occurs during the synthesis of peptides and other compounds in the chemical, pharmaceutical, and recombinant DNA industries.

### ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

No studies on the absorption, distribution, metabolism, or excretion of disopropylcarbodiimide in experimental animals or humans were found in a review of the published literature.

NTP conducted absorption and distribution studies via the dermal route in rats and mice (Appendix L). Data indicated that only a small percentage of the radiolabeled dose was absorbed (approximately 1% to 2%) due to the high volatility of diisopropylcarbodiimide. The majority of the dose was recovered in the charcoal-impregnated appliances used to cover the site of application. Approximately 90.7% of the dose was unabsorbed and 90.5% was contained in the appliance and skin wash. Less than 0.2% of the administered dose was recovered from any tissue site. The majority of the dose rapidly volatilized from the dose site and was not available for absorption.

#### **TOXICITY**

#### **Experimental Animals**

The oral LD<sub>50</sub> for diisopropylcarbodiimide in mice is 36 mg/kg (RTECS, 1991a). While the chemistry of diisopropylcarbodiimide and dicyclohexylcarbodiimide are virtually identical, interactions with biomolecules differ. Two cases in point involve ATPase. The Ca<sup>2+</sup>-ATPase of sarcoplasmic reticulum vesicles is readily inactivated by diisopropylcarbodiimide (Murphy, 1981). Although the related chemical, dicyclohexylcarbodiimide, readily inactivates *Escherichia coli* BF1-ATPase at 0.05 mM, diisopropylcarbodiimide shows almost no inactivation at this concentration (Satre *et al.*, 1979).

#### Humans

Delayed, temporary blindness has been reported in a worker following an acute occupational exposure to diisopropylcarbodiimide vapor (Moyer, 1990). The worker had cleaned up a 1 L spill of diisopropylcarbodiimide while wearing a respirator, laboratory coat, and impervious gloves. Approximately 12 to 18 hours later, the worker experienced hazy vision followed by mild pain that maximized 34 hours after the exposure. Damage to the outer layer of the cornea resulted in blindness that subsided over a 2-week period. Ellis (1991) noted that this injury

resembled mild to moderate mustard gas injury, for which the postulated mechanism of action is alkylation of nucleophilic functional groups of intracellular components, occurring within minutes of exposure and leading to cellular dysfunction and even cell death. This author noted that it is reasonable to assume that all alkylcarbodiimides are capable of functioning as alkylating agents and are therefore potential vesicants and carcinogens.

#### REPRODUCTIVE AND DEVELOPMENTAL TOXICITY

#### **Experimental Animals**

No information on the reproductive or developmental toxicity of diisopropylcarbodiimide in animals was found in the literature, but a single oral reproductive study in rats of the related chemical carbodiimide has been reported (RTECS, 1991b). In this study, a dose of 2,450 mg carbodiimide/kg caused preimplantation mortality, 1,750 mg/kg caused paternal effects (testes, epididymis, sperm duct, prostate, seminal vesicle, Cowper's gland, and accessory glands), 208 mg/kg affected postimplantation mortality and the live birth index. In the same study, 2,600 mg/kg affected newborn rats (live birth index, growth statistics, and delayed effects).

#### Humans

No information on the reproductive or developmental toxicity of diisopropylcarbodiimide in humans was found in the literature.

#### **CARCINOGENICITY**

No data on the carcinogenicity of diisopropylcarbodiimide in animals or epidemiology studies or case reports associating diisopropylcarbodiimide exposure with cancer risk in humans were found in the literature.

#### **GENETIC TOXICITY**

Witt et al. (1999) described the results of a series of in vivo mutagenicity tests with diisopropylcarbodiimide. The chemical was shown to induce micronuclei in erythrocytes of male and female mice treated by skin painting for a period of 3 months. An additional subchronic micronucleus investigation was performed with diisopropylcarbodiimide in male mice, in which the chemical was administered by skin painting for 4 months and weekly or biweekly counts of micronucleated erythrocytes, as well as percent polychromatic erythrocytes (% PCEs), were obtained. Results of this study confirmed the activity of diisopropylcarbodiimide that was observed in the 3-month skin painting study. However, short-term tests using a three-injection protocol with diisopropylcarbodiimide in rats and in mice showed no evidence of micronucleus induction in bone marrow PCEs. Results of a single-injection mouse micronucleus test with disopropylcarbodiimide gave results that were concluded to be equivocal; frequencies of micronucleated PCEs were significantly increased in peripheral blood samples obtained 48 hours after injection, but in bone marrow, the frequency of micronucleated PCEs, although elevated at 24 and 48 hours in two of three trials, did not differ significantly from the control levels. The authors suggested that one interpretation of these results might be that diisopropylcarbodiimide induces chromosomal damage in erythrocytes soon after treatment, and that, due to the kinetics of erythrocyte maturation, this damage is detectable as micronucleated cells in blood but not bone marrow at the standard time points assayed for micronucleus induction. Alternatively, the spleen might be a target organ for diisopropylcarbodiimide, and damage to splenic cells might result in increased frequencies of micronucleated erythrocytes in the circulating erythrocyte population compared to the population of erythrocytes residing in the bone marrow.

#### STUDY RATIONALE

Diisopropylcarbodiimide and dicyclohexylcarbodiimide were nominated by the National Cancer Institute as representatives of the carbodiimide chemical class. The results of the dicyclohexylcarbodiimide studies will be reported separately.

Diisopropylcarbodiimide has been used in industry as a stabilizing, coupling, and condensing agent. The potential for human exposure exists during the synthesis of polypeptides and other chemicals in the chemical and pharmaceutical industries and during protein synthesis in the recombinant DNA industry. Evidence on which to evaluate the potential for human carcinogenicity is lacking. No epidemiological studies or case reports associating diisopropylcarbodiimide with a cancer risk in humans have been reported. No information was found on the carcinogenicity in experimental animals, genotoxicity, teratogenicity, or metabolism of diisopropylcarbodiimide.

In the current studies, a dermal route of exposure was chosen to mimic the primary route of human exposure. In addition to these studies, the NTP has also studied diisopropylcarbodiimide in Tg.AC hemizygous and p53 haploinsufficient genetically modified mouse models (NTP, 2005).

# MATERIALS AND METHODS

#### PROCUREMENT AND CHARACTERIZATION

#### Diisopropylcarbodiimide

Diisopropylcarbodiimide was obtained from Aldrich Chemical Company (Milwaukee, WI) in three lots.

Lot 01207BG was used during the 2-week and 3-month studies; lot 13016JS was used during the 2-year studies.

One additional lot (09330DR) was used solely for dose formulation stability studies and was not used in the animal studies. Identity and purity analyses were conducted by the analytical chemistry laboratory at Midwest Research Institute (Kansas City, MO) and by the study laboratories at Microbiological Associates, Inc. (Bethesda, MD; 2-week and 3-month studies), and Southern Research Institute (Birmingham, AL; 2-year studies); physical properties, moisture content, and stability of the bulk diisopropylcarbodiimide were determined by the analytical chemistry laboratory. Reports on analyses performed in support of the diisopropylcarbodiimide studies are on file at the National Institute of Environmental Health Sciences.

Lot 01207BG, a colorless liquid, was identified as diisopropylcarbodiimide by the study laboratory using infrared (IR) spectroscopy. Lot 13016JS was identified as diisopropylcarbodiimide by the study laboratory using IR and proton nuclear magnetic resonance (NMR) spectroscopy and by the analytical chemistry laboratory using IR, proton NMR, and ultraviolet/visible spectroscopy and gas chromatography (GC)/mass spectrometry. All spectra were consistent with the structure of diisopropylcarbodiimide and with literature references.

The purity of lot 01207BG was determined by the study laboratory using GC. The purity of lot 13016JS was determined by the study laboratory using GC and by the analytical chemistry laboratory using thin layer chromatography (TLC) and GC. The moisture content of lot 13016JS was determined by the analytical chemistry laboratory using Karl Fischer titration; the boiling point and relative density of this lot were also measured by the analytical chemistry laboratory.

For lot 01207BG, GC indicated a major peak and five impurity peaks with areas ranging from 0.05% to 0.27% of the total peak area. Fourteen minor impurities were present in the sample chromatograms. The overall purity of lot 01207BG was determined to be 99.35%.

For lot 13016JS, the boiling point and relative density were consistent with the literature values for diisopropylcarbodiimide. Karl Fischer titration indicated 0.06% water in the bulk chemical. TLC detected a major, a minor, and two trace spots. GC indicated a relative purity of 102% when compared to a frozen reference sample and a mean purity of 99.6% when calculated on an area percent. GC indicated a major peak and five impurity peaks with a combined area of approximately 0.5% of the total peak area; the purity of the test article was determined to be approximately 99.5%. The overall purity of lot 13016JS was determined to be greater than 99%.

The analytical chemistry laboratory conducted accelerated stability studies of lot 13016JS with samples stored for 2 weeks in amber vials with Teflon®-lined septa at approximately 5°, 25°, and 60° C compared to frozen samples from the same lot stored at –20° C. Analysis using GC indicated that the test article was stable when protected from light at temperatures up to approximately 60° C for 2 weeks. To ensure stability, the bulk chemical was stored at room temperature under nitrogen, protected from light as recommended by the manufacturer. Stability was monitored by the study laboratories during the 3-month and 2-year studies using GC; no degradation of the bulk chemical was detected.

#### **Anhydrous Ethanol**

Anhydrous ethanol was obtained in two lots from Aldrich Chemical Company for use during the 2-year studies. Identity and purity analyses of both lots were conducted by the study laboratory. The chemical, a clear liquid, was identified as ethanol using IR spectroscopy; the sample spectra were a good match for the reference spectrum of ethanol. The purity of each lot was determined using GC. No impurities were detected that exceeded a relative concentration of 0.1% in either lot.

#### PREPARATION AND ANALYSIS OF DOSE FORMULATIONS

Except for the 242 mg (rats) and 81 mg (mice) dose formulations, which were used neat in the 2-week studies, the dose formulations were prepared by mixing diisopropylcarbodiimide and anhydrous ethanol to give the required concentrations; formulations were prepared once for the 2-week studies and weekly, biweekly, or monthly for the 3-month and 2-year studies. The dose formulations were stored at room temperature (2-week and 3-month studies) or refrigerated (2-year studies) for up to 28 days.

Because the dose formulations were the neat test article or true solutions of the test article in ethanol, homogeneity studies were not performed. A stability study of a 10 mg/mL dose formulation of lot 01207BG was conducted by the study laboratory using GC; stability was confirmed for at least 28 days for the dose formulation stored at ambient temperature in sealed containers. In a subsequent 35-day dose formulation stability study of lot 09330DR (not used in the animal studies), the analytical chemistry laboratory utilized GC to determine that a 2 mg/mL dose formulation was stable for at least 21 days when stored refrigerated in sealed glass containers and for up to 3 hours when exposed to light at ambient temperature. The study laboratory conducted a stability study of 5.0 and 20.0 mg/mL dose formulations of lot 13016JS and determined that the formulations were stable for at least 35 days when stored refrigerated in sealed glass containers.

Periodic analyses of the dose formulations of diisopropylcarbodiimide were conducted by the study laboratories using GC. During the 2-week studies, the dose formulations were analyzed once; all five dose formulations for rats and mice were within 10% of the target concentrations. Animal room samples of these dose formulations were also analyzed; all five of the animal room samples for rats and mice were within 10% of the target concentrations. Dose formulations were analyzed at the beginning, midpoint, and end of the 3-month studies; animal room samples of these dose formulations were also analyzed. Of the dose formulations analyzed, all 14 for rats and 13 for mice were within 10% of the target concentrations; all 12 and 13 of the animal room samples for rats and mice, respectively, were within 10% of the target concentrations. During the 2-year studies, the dose formulations were generally analyzed every 8 to 12 weeks; animal room samples of these dose formulations were also analyzed. All

33 of the dose formulations analyzed and used for rats and mice were within 10% of the target concentrations. Of the animal room samples analyzed, 92% (11/12) of those for rats and 83% (10/12) of those for mice were within 10% of the target concentrations.

#### 2-WEEK STUDIES

Male and female F344/N rats and B6C3F<sub>1</sub> mice were obtained from Taconic Laboratory Animals and Services (Germantown, NY). On receipt, the animals were approximately 5 weeks old. Animals were quarantined for 11 (rats) or 13 (mice) days; rats were 6 weeks old on the first day of the study and mice were 7 weeks old. Before the studies began, two male and two female rats and mice were randomly selected for parasite evaluation and gross observation for evidence of disease. Groups of five male and five female rats received dermal applications of 0, 3, 9, 27, 81, or 242 mg diisopropylcarbodiimide per animal and groups of five male and five female mice received dermal applications of 0, 1, 3, 9, 27, or 81 mg per animal 5 days a week for 16 days. The high dose was applied neat as 0.3 mL (rats) or 0.1 mL (mice) of test chemical. All other doses were dissolved in ethanol to yield dosing values of 0.3 or 0.1 mL for application to rats or mice, respectively. Vehicle control rats and mice received ethanol only. Solutions or neat chemical were applied to the shaved dorsal surface of rats and mice. Feed and water were available *ad libitum*. Rats and mice were housed individually. Clinical findings and body weights were recorded on days 1 and 8 and at study termination. Details of the study design and animal maintenance are summarized in Table 1.

Necropsies were performed on all rats and mice. The heart, right kidney, liver, lung, right testis, and thymus were weighed and examined for gross lesions. Histopathologic examinations were performed on rats and mice in the 0, 10, 30, and 90 mg/mL groups. Table 1 lists the tissues and organs examined.

#### **3-MONTH STUDIES**

The 3-month studies were conducted to evaluate the cumulative toxic effects of repeated exposure to disopropylcarbodiimide and to determine the appropriate exposure concentrations to be used in the 2-year studies.

Male and female F344/N rats and B6C3F<sub>1</sub> mice were obtained from Taconic Laboratory Animals and Services (Germantown, NY). On receipt, rats and female mice were 5 weeks old and male mice were 6 weeks old. Rats were quarantined for 12 (males) or 13 (females) days and mice were quarantined for 14 (males) or 15 (females) days. Rats and female mice were 7 weeks old and male mice were 8 weeks old on the first day of the studies. Before initiation of the studies, five male and five female rats and mice were randomly selected for parasite evaluation and gross observation for evidence of disease. At the end of the studies, serologic analyses were performed on five male and five female control rats and sentinel mice using the protocols of the NTP Sentinel Animal Program (Appendix K).

Groups of 10 male and 10 female core study rats received dermal applications of 0, 10, 20, 40, 80, or 160 mg diisopropylcarbodiimide per kilogram body weight. Groups of 10 male and 10 female mice received dermal applications of 0, 17.5, 35, 70, 140, or 280 mg/kg. All doses were administered in ethanol, in volumes of 0.5 or 2.0 mL/kg for rats and mice respectively; vehicle control animals received ethanol only. Single daily doses were applied 5 days per week for 13 weeks to a shaved dorsal area posterior of the scapulae to the base of the tail. Additional groups of 10 male and 10 female rats designated for clinical pathology evaluations on days 3 and 22 received the same dermal exposures as the core study rats. Feed and water were available *ad libitum*. Rats and mice were housed individually. Body weights and clinical findings for rats and mice were recorded initially, weekly, and at the end of the studies. Details of the study design and animal maintenance are summarized in Table 1.

Blood was collected for hematology and clinical chemistry analyses from clinical pathology study rats on days 3 and 22 and from surviving core study rats at study termination. Blood was collected for hematology analyses from

surviving mice at study termination. At all time points, the animals were anesthetized with a 70% CO<sub>2</sub>/30% O<sub>2</sub> mixture and blood was collected from the retroorbital sinus. Blood for hematology analyses was placed in tubes containing EDTA as the anticoagulant. Erythrocyte, platelet, and leukocyte counts, automated hematocrit values, hemoglobin concentration, mean cell volume, mean cell hemoglobin, and mean cell hemoglobin concentration were determined using a Serono-Baker System 9010 hematology analyzer (Serono-Baker Diagnostics, Allentown, PA). Manual hematocrit determinations were performed using an Adams Microhematocrit Centrifuge, Model CT2900. Differential leukocyte counts and erythrocyte and leukocyte morphologies were determined microscopically from blood smears stained with a modified Wright's stain on a Hema-Tek slide stainer (Miles Laboratory, Ames Division, Elkhart, IN). Reticulocytes were stained with new methylene blue and counted microscopically. For clinical chemistry analyses, blood samples were placed into untreated serum separator tubes, centrifuged, and the serum samples were analyzed using a Hitachi 717 chemistry analyzer (Boehringer Mannheim, Indianapolis, IN) and commercially available reagents. The parameters measured are listed in Table 1.

At the end of the 3-month studies, samples were collected for sperm motility and vaginal cytology evaluations on core study rats in the 0, 10, 20, and 40 mg/kg groups and mice in the 0, 17.5, 35, and 70 mg/kg groups. The parameters evaluated are listed in Table 1. For 12 consecutive days prior to scheduled terminal sacrifice, the vaginal vaults of the females were moistened with saline, if necessary, and samples of vaginal fluid and cells were stained. Relative numbers of leukocytes, nucleated epithelial cells, and large squamous epithelial cells were determined and used to ascertain estrous cycle stage (i.e., diestrus, proestrus, estrus, and metestrus). Male animals were evaluated for sperm count and motility. The left testis and left epididymis were isolated and weighed. The tail of the epididymis (cauda epididymis) was then removed from the epididymal body (corpus epididymis) and weighed. Test yolk (rats) or modified Tyrode's buffer (mice) was applied to slides and a small incision was made at the distal border of the cauda epididymis. The sperm effluxing from the incision were dispersed in the buffer on the slides, and the numbers of motile and nonmotile spermatozoa were counted for five fields per slide by two observers. Following completion of sperm motility estimates, each left cauda epididymis was placed in buffered saline solution. Caudae were finely minced, and the tissue was incubated in the saline solution and then heat fixed

at 65° C. Sperm density was then determined microscopically with the aid of a hemacytometer. To quantify spermatogenesis, the testicular spermatid head count was determined by removing the tunica albuginea and homogenizing the left testis in phosphate-buffered saline containing 10% dimethyl sulfoxide. Homogenization-resistant spermatid nuclei were counted with a hemacytometer.

Necropsies were performed on all core study animals. The heart, right kidney, liver, lung, right testis, and thymus were weighed. Tissues for microscopic examination were fixed and preserved in 10% neutral buffered formalin, processed and trimmed, embedded in paraffin, sectioned to a thickness of 5 to 6  $\mu$ m, and stained with hematoxylin and eosin (H&E). Complete histopathologic examinations were performed on 0, 40, 80, and 160 mg/kg core study rats and 0, 70, 140, and 280 mg/kg mice. Table 1 lists the tissues and organs routinely examined.

## 2-YEAR STUDIES

#### **Study Design**

Groups of 50 male and 50 female rats and mice received dermal applications of 0, 10, 20, or 40 mg/kg. All doses were administered in ethanol, in volumes of 0.5 or 2.0 mL/kg for rats and mice respectively; vehicle control animals received ethanol only. Single daily doses were applied 5 days per week for 105 weeks to a clipped area in the interscapular region of the back using a positive displacement micropipetter.

#### **Source and Specification of Animals**

Male and female F344/N rats and B6C3F<sub>1</sub> mice were obtained from Taconic Laboratory Animals and Services (Germantown, NY). Animals were quarantined for 12 days. Before initiation of the studies, five male and five female rats and mice were randomly selected for parasite evaluation and gross observation for evidence of disease. Rats were 6 weeks old and mice were 5 or 6 weeks old on the first day of the studies. The health of the animals was monitored during the studies according to the protocols of the NTP Sentinel Animal Program (Appendix K).

#### **Animal Maintenance**

Rats and mice were housed individually. Feed and water were available *ad libitum*. Cages were rotated weekly, and racks were rotated every 2 weeks. Further details of animal maintenance are given in Table 1. Information on feed composition and contaminants is provided in Appendix J.

#### **Clinical Examinations and Pathology**

Clinical findings were recorded every 4 weeks beginning week 5. Body weights were recorded initially, weekly for 13 weeks, at 4-week intervals thereafter, and at the end of the studies.

Complete necropsies and microscopic examinations were performed on all rats and mice. At necropsy, all organs and tissues were examined for grossly visible lesions, and all major tissues were fixed and preserved in 10% neutral buffered formalin, processed and trimmed, embedded in paraffin, sectioned to a thickness of 4 to 6  $\mu$ m, and stained with H&E for microscopic examination. For all paired organs (e.g., adrenal gland, kidney, ovary), samples from each organ were examined. Tissues examined microscopically are listed in Table 1.

Microscopic evaluations were completed by the study laboratory pathologist, and the pathology data were entered into the Toxicology Data Management System. The slides, paraffin blocks, and residual wet tissues were sent to the NTP Archives for inventory, slide/block match, and wet tissue audit. The slides, individual animal data records, and pathology tables were evaluated by an independent quality assessment laboratory. The individual animal records and tables were compared for accuracy, the slide and tissue counts were verified, and the histotechnique was evaluated. For the 2-year studies, a quality assessment pathologist evaluated slides from all tumors and all potential target organs, which included the brain, eye, and skin of male and female rats and mice; the lung of male and female rats; the spleen and testis of male rats; the mammary gland of female rats; the mesentery and peritoneum of male mice; and the adrenal gland of female mice. Preceding the Pathology Working Group (PWG) report for the 2-year rat study, the primary and reviewing pathologists had identified focal brain hemorrhages in some animals, particularly in the 40 mg/kg males. These lesions were of an acute nature, probably

occurring at or near the time of terminal sacrifice. Clinically, some of these animals had early-occurring seizures. In an effort to discover possible brain lesions related to seizure activity, a detailed post-neuropathological review was conducted by the PWG. The review for the 2-year study included an evaluation of the three standard H&E brain sections for all control, mid-dose, and high-dose male rats. Based on the 2-year neuropathology findings, the 3 month male and female rat brain slides were reevaluated and read to a no-effect level. In both the 2-year and 3-month studies, neuronal necrosis and fibrinoid arteriole lesions were identified which were sometimes associated with vascular hemorrhages. Fibrinoid arteriole necrosis was confirmed with the use of Periodic Acid Schiff staining on selected rats from the 2-year study.

The quality assessment report and the reviewed slides were submitted to the NTP Pathology Working Group (PWG) chairperson, who reviewed the selected tissues and addressed any inconsistencies in the diagnoses made by the laboratory and quality assessment pathologists. Representative histopathology slides containing examples of lesions related to chemical administration, examples of disagreements in diagnoses between the laboratory and quality assessment pathologists, or lesions of general interest were presented by the chairperson to the PWG for review. The PWG consisted of the quality assessment pathologist and other pathologists experienced in rodent toxicologic pathology. This group examined the tissues without any knowledge of dose groups or previously rendered diagnoses. When the PWG consensus differed from the opinion of the laboratory pathologist, the diagnosis was changed. Final diagnoses for reviewed lesions represent a consensus between the laboratory pathologist, reviewing pathologist(s), and the PWG. Details of these review procedures have been described, in part, by Maronpot and Boorman (1982) and Boorman *et al.* (1985). For subsequent analyses of the pathology data, the decision of whether to evaluate the diagnosed lesions for each tissue type separately or combined was generally based on the guidelines of McConnell *et al.* (1986).

# 2-Week Studies 3-Month Studies

#### Histopathology

Histopathology was performed on 0, 3, 9, and 27 mg rats and 0, 1, 3, and 9 mg mice. In addition to gross lesions and tissue masses, the following tissues were examined: brain, kidney, liver, lung, skin, and spinal cord.

Complete histopathology was performed on core study rats exposed to 0, 40, 80, or 160 mg/kg and mice exposed to 0, 70, 140, or 280 mg/kg. In addition to gross lesions and tissue masses, the following tissues were examined: adrenal gland, bone with marrow. brain, clitoral gland, esophagus, gallbladder (mice only), heart with aorta, large intestine (cecum, colon, rectum), small intestine (duodenum, jejunum, ileum), kidney, liver, lung, lymph nodes (mandibular and mesenteric), mammary gland, nose, ovary, pancreas, pancreatic islets, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, skin, spleen, stomach (forestomach and glandular), testis with epididymis and seminal vesicle, thymus, thyroid gland, trachea, urinary bladder, and uterus. In the remaining groups, the skin of rats and mice and the brain, heart, spleen, and thymus of rats were examined.

Complete histopathology was performed on all rats and mice. In addition to gross lesions and tissue masses, the following tissues were examined: adrenal gland, bone with marrow, brain, clitoral gland, esophagus, eye, gallbladder (mice only), harderian gland, heart with aorta, large intestine (cecum, colon, rectum), small intestine (duodenum, jejunum, ileum), kidney, liver, lung, lymph nodes (mandibular, mesenteric), mammary gland, nose, ovary, pancreas, pancreatic islets, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, sciatic nerve (rats only), skin, spinal cord (rats only), spleen, stomach (forestomach and glandular), testis with epididymis and seminal vesicle, thymus, thyroid gland, trachea, urinary bladder, and uterus

2-Year Studies

Sperm Motility and Vaginal Cytology

None

At the end of the studies, core study rats from the 0, 10, 20, and 40 mg/kg groups and mice from the 0, 17.5, 35, and 70 mg/kg groups were evaluated for reproductive parameters. The following parameters were evaluated: spermatid heads per testis and per gram testis, spermatid count, and epididymal spermatozoal motility and concentration. The left cauda, left epididymis, and left testis were weighed. Vaginal samples were collected for up to 12 consecutive days prior to the end of the studies. Estrous cycle length and the relative frequency of estrous stages were measured.

None

# STATISTICAL METHODS

# **Survival Analyses**

The probability of survival was estimated by the product-limit procedure of Kaplan and Meier (1958) and is presented in the form of graphs. Animals found dead of other than natural causes or missing were censored from the survival analyses; animals dying from natural causes were not censored. Statistical analyses for possible doserelated effects on survival used Cox's (1972) method for testing two groups for equality and Tarone's (1975) life table test to identify dose-related trends. All reported P values for the survival analyses are two sided.

#### **Calculation of Incidence**

The incidences of neoplasms or nonneoplastic lesions are presented in Tables A1, A5, B1, B4, C1, C4, D1, and D5 as the numbers of animals bearing such lesions at a specific anatomic site and the numbers of animals with that site examined microscopically. For calculation of statistical significance, the incidences of most neoplasms (Tables A3, B3, C3, and D3) and all nonneoplastic lesions are given as the numbers of animals affected at each site examined microscopically. However, when macroscopic examination was required to detect neoplasms in certain tissues (e.g., harderian gland, intestine, mammary gland, and skin) before microscopic evaluation, or when neoplasms had multiple potential sites of occurrence (e.g., leukemia or lymphoma), the denominators consist of the number of animals on which a necropsy was performed. Tables A3, B3, C3, and D3 also give the survival-adjusted neoplasm rate for each group and each site-specific neoplasm. This survival-adjusted rate (based on the Poly-3 method described below) accounts for differential mortality by assigning a reduced risk of neoplasm, proportional to the third power of the fraction of time on study, only to site-specific, lesion-free animals that do not reach terminal sacrifice.

### Analysis of Neoplasm and Nonneoplastic Lesion Incidences

The Poly-k test (Bailer and Portier, 1988; Portier and Bailer, 1989; Piegorsch and Bailer, 1997) was used to assess neoplasm and nonneoplastic lesion prevalence. This test is a survival-adjusted quantal-response procedure that modifies the Cochran-Armitage linear trend test to take survival differences into account. More specifically, this method modifies the denominator in the quantal estimate of lesion incidence to approximate more closely the total

number of animal years at risk. For analysis of a given site, each animal is assigned a risk weight. This value is one if the animal had a lesion at that site or if it survived until terminal sacrifice; if the animal died prior to terminal sacrifice and did not have a lesion at that site, its risk weight is the fraction of the entire study time that it survived, raised to the kth power.

This method yields a lesion prevalence rate that depends only upon the choice of a shape parameter for a Weibull hazard function describing cumulative lesion incidence over time (Bailer and Portier, 1988). Unless otherwise specified, a value of k=3 was used in the analysis of site-specific lesions. This value was recommended by Bailer and Portier (1988) following an evaluation of neoplasm onset time distributions for a variety of site-specific neoplasms in control F344 rats and B6C3F<sub>1</sub> mice (Portier *et al.*, 1986). Bailer and Portier (1988) showed that the Poly-3 test gave valid results if the true value of k was anywhere in the range from 1 to 5. A further advantage of the Poly-3 method is that it does not require lesion lethality assumptions. Variation introduced by the use of risk weights, which reflect differential mortality, was accommodated by adjusting the variance of the Poly-3 statistic as recommended by Bieler and Williams (1993).

Tests of significance included pairwise comparisons of each dosed group with controls and a test for an overall dose-related trend. Continuity-corrected Poly-3 tests were used in the analysis of lesion incidence, and reported P values are one sided. The significance of lower incidences or decreasing trends in lesions is represented as 1–P with the letter N added (e.g., P=0.99 is presented as P=0.01N).

# **Analysis of Continuous Variables**

Two approaches were employed to assess the significance of pairwise comparisons between dosed and control groups in the analysis of continuous variables. Organ and body weight data, which have approximately normal distributions, were analyzed with the parametric multiple comparison procedures of Dunnett (1955) and Williams (1971, 1972). Hematology, clinical chemistry, spermatid, and epididymal spermatozoal data, which have typically skewed distributions, were analyzed using the nonparametric multiple comparison methods of Shirley (1977)

(as modified by Williams, 1986) and Dunn (1964). Jonckheere's test (Jonckheere, 1954) was used to assess the significance of the dose-related trends and to determine whether a trend-sensitive test (Williams' or Shirley's test) was more appropriate for pairwise comparisons than a test that does not assume a monotonic dose-related trend (Dunnett's or Dunn's test). Prior to statistical analysis, extreme values identified by the outlier test of Dixon and Massey (1957) were examined by NTP personnel, and implausible values were eliminated from the analysis.

Average severity values were analyzed for significance with the Mann-Whitney U test (Hollander and Wolfe, 1973). Because vaginal cytology data are proportions (the proportion of the observation period that an animal was in a given estrous stage), an arcsine transformation was used to bring the data into closer conformance with a normality assumption. Treatment effects were investigated by applying a multivariate analysis of variance (Morrison, 1976) to the transformed data to test for simultaneous equality of measurements across exposure concentrations.

#### **Historical Control Data**

The concurrent control group represents the most valid comparison to the treated groups and is the only control group analyzed statistically in NTP bioassays. However, historical control data are often helpful in interpreting potential treatment-related effects, particularly for uncommon or rare neoplasm types. For meaningful comparisons, the conditions for studies in the historical database must be generally similar. One significant factor affecting the background incidence of neoplasms at a variety of sites is diet. In 1995, the NTP incorporated a new diet (NTP-2000) that contains less protein and more fiber and fat than the NIH-07 diet previously used in toxicity and carcinogenicity studies (Rao, 1996, 1997). The current NTP historical database contains all studies that use the NTP-2000 diet with histopathology findings completed up to the present. A second potential source of variability is route of administration. In general, the historical database for a given study will include studies using the same route of administration, and the overall incidences of neoplasms for all routes of administration are included for comparison. Because the only dermal studies using an ethanol vehicle in the current historical database are the studies presented in this Technical Report, only overall incidences for all routes of administration have been used for historical comparison in this Technical Report.

# **QUALITY ASSURANCE METHODS**

The 3-month and 2-year studies were conducted in compliance with Food and Drug Administration Good

Laboratory Practice Regulations (21 CFR, Part 58). In addition, as records from the 2-year studies were submitted to the NTP Archives, these studies were audited retrospectively by an independent quality assurance contractor.

Separate audits covered completeness and accuracy of the pathology data, pathology specimens, final pathology tables, and a draft of this NTP Technical Report. Audit procedures and findings are presented in the reports and are on file at NIEHS. The audit findings were reviewed and assessed by NTP staff, and all comments were resolved or otherwise addressed during the preparation of this Technical Report.

# GENETIC TOXICOLOGY

The genetic toxicity of diisopropylcarbodiimide was assessed by testing the ability of the chemical to induce mutations in various strains of *Salmonella typhimurium*, micronucleated erythrocytes in rat and mouse bone marrow, and increases in the frequency of micronucleated erythrocytes in mouse peripheral blood. The protocols for these studies and the results are given in Appendix E.

The genetic toxicity studies have evolved from an earlier effort by the NTP to develop a comprehensive database permitting a critical anticipation of a chemical's carcinogenicity in experimental animals based on numerous considerations, including the molecular structure of the chemical and its observed effects in short-term *in vitro* and *in vivo* genetic toxicity tests (structure-activity relationships). The short-term tests were originally developed to clarify proposed mechanisms of chemical-induced DNA damage based on the relationship between electrophilicity and mutagenicity (Miller and Miller, 1977) and the somatic mutation theory of cancer (Straus, 1981; Crawford, 1985). However, it should be noted that not all cancers arise through genotoxic mechanisms.

DNA reactivity combined with *Salmonella* mutagenicity is highly correlated with induction of carcinogenicity in multiple species/sexes of rodents and at multiple tissue sites (Ashby and Tennant, 1991). A positive response in

the *Salmonella* test was shown to be the most predictive *in vitro* indicator for rodent carcinogenicity (89% of the *Salmonella* mutagens are rodent carcinogens) (Tennant *et al.*, 1987; Zeiger *et al.*, 1990). Additionally, no battery of tests that included the *Salmonella* test improved the predictivity of the *Salmonella* test alone. However, these other tests can provide useful information on the types of DNA and chromosomal damage induced by the chemical under investigation.

The predictivity for carcinogenicity of a positive response in acute *in vivo* bone marrow chromosome aberration or micronucleus tests appears to be less than that in the *Salmonella* test (Shelby *et al.*, 1993; Shelby and Witt, 1995). However, clearly positive results in long-term peripheral blood micronucleus tests have high predictivity for rodent carcinogenicity (Witt *et al.*, 2000); negative results in this assay do not correlate well with either negative or positive results in rodent carcinogenicity studies. Because of the theoretical and observed associations between induced genetic damage and adverse effects in somatic and germ cells, the determination of *in vivo* genetic effects is important to the overall understanding of the risks associated with exposure to a particular chemical. Most organic chemicals that are identified by the International Agency for Research on Cancer as human carcinogens, other than hormones, are genotoxic. The vast majority of these are detected by both the *Salmonella* assay and rodent bone marrow cytogenetics tests (Shelby, 1988; Shelby and Zeiger, 1990).

# **RESULTS**

# RATS

# 2-WEEK STUDY

No toxicity data were available on diisopropylcarbodiimide in the literature. Therefore, the high dose group in this study received 0.3 mL of neat diisopropylcarbodiimide (242 mg/animal). For the lower dose groups, diisopropylcarbodiimide was diluted with ethanol and administered in concentrations of 3, 9, 27, or 81 mg/animal; each animal received a total volume of 0.3 mL. The vehicle controls were administered 0.3 mL of ethanol only.

All rats in the 27, 81, and 242 mg groups died before the end of the study (Table 2). Of the surviving groups, final body weights were similar to those of the vehicle controls. Clinical findings included convulsions/seizures, nasal/eye discharge, tremors, and comatose conditions in 81 and 242 mg rats, and lethargy, ataxia, and abnormal breathing in 27 mg rats. There were no significant differences in organ weights between surviving dosed groups and the vehicle control groups (Table G1).

The incidences of epidermal hyperplasia at the site of application in 9 and 27 mg males and 27 mg females were significantly greater than those in the vehicle controls; the incidences of hyperkeratosis in 3 and 9 mg males and 9 mg females were also significantly increased (Table 3).

# **3-MONTH STUDIES**

All 160 mg/kg male and female rats were sacrificed moribund or died within the first week of the study (Table 4). All 80 mg/kg males and females died or were found moribund by day 59. Significant decreases in body weight gain occurred in 40 mg/kg males and females, and a significant decrease in final mean body weight occurred in 40 mg/kg females (Table 4). Clinical findings in groups administered 40 mg/kg or more generally included irritation of the skin at the site of application, seizures, ataxia, abnormal breathing, ruffled fur, thinness, and lethargy.

Number of animals surviving at 3 months/number initially in group

Weights and weight changes are given as mean  $\pm$  standard error. Subsequent calculations are based on animals surviving to the end of the study.

d Week of death: 3, 3, 3, 4, 4, 4, 4, 4, 5, 7 Week of death: 1

e Week of death: 4, 5, 5, 5, 6, 6, 6, 6, 9

The hematology and clinical chemistry data are listed in Table F1. Scattered changes occurred in the hematology and clinical chemistry variables. In general, the changes were sporadic and minimal and were not considered toxicologically relevant. At the end of the 3-month study, the absolute liver weight of 40 mg/kg females was significantly less than that of the vehicle controls (Table G2). All other organ weights were similar to those of vehicle controls. There were no significant differences in reproductive tissue parameters or estrous cycle characterization between treated and vehicle control groups (Tables H1 and H2).

Significantly increased incidences of skin lesions at the site of application included epidermal hyperplasia of minimal to mild severity in all dosed groups of males (except 160 mg/kg) and 40 mg/kg or greater females, epidermal necrosis in 160 mg/kg males (mild severity) and females (minimal severity), and minimal to moderate chronic active inflammation in 80 and 160 mg/kg males and females (Table 5). In the brain, the incidences of minimal focal edema and focal necrosis in 80 mg/kg males and females and minimal focal hemorrhage in 80 mg/kg females and 160 mg/kg males and females were significantly greater than those of the vehicle controls.

*Dose Selection Rationale:* Based on mortality and body weight changes, 40 mg/kg per day was selected as the high dose for male and female F344/N rats in the 2-year study of diisopropylcarbodiimide.

# 2-YEAR STUDIES

#### Survival

Estimates of 2-year survival probabilities for rats are shown in Table 6 and in the Kaplan-Meier survival curves (Figure 1). Survival of 20 mg/kg males was significantly greater than that of the vehicle controls; survival of all dosed groups of females was similar to that of the vehicle controls.

Administered Diisopropylcarbodiimide Dermally for 2 Years

# **Body Weights and Clinical Findings**

Body weights of 40 mg/kg males were markedly less than those of vehicle controls after week 13 and 40 mg/kg females were slightly less after week 17 (Figure 2; Tables 7 and 8). At the end of the study, body weights of 40 mg/kg males and females were 79% or 88% of those of the vehicle control groups, respectively. Clinical findings frequently observed in 40 mg/kg male rats included ataxia, excitability, impaired gait, low muscle tone, abnormal breathing, lethargy, vocalization, and seizures (Table 9). Few clinical findings were recorded for females.

Primarily during the second year of the study, seizures were observed sporadically in some male and female rats from each dose group, including the vehicle controls. More females were affected than males (females: vehicle controls, 7/50; 10 mg/kg, 9/50; 20 mg/kg, 17/50; 40 mg/kg, 6/50; males: 4/50, 4/50, 9/50, 11/50), and the first onset was earlier in males (week 36) than in females (week 60). Most seizures were mild, characterized by an abnormal hunched posture and chewing movements sometimes accompanied by clonic spasms of alternate muscle contraction and relaxation, lasting approximately 30 seconds with a rapid recovery. Uncommon seizures of greater severity produced more pronounced jerking lasting up to 60 seconds with a recovery time of 2 minutes. Most seizure-prone animals had multiple episodes (two to 13). Eleven 40 mg/kg males experienced seizures; of these, seizures in six were considered related to chemical administration because of early onset (weeks 36 to 44) and other neurological signs concurrently observed (Table 9). The incidences and number of episodes per rat did not appear related to dose in any other rats.

Similar, sporadic seizures have been observed in F344/N rats in six other NTP inhalation or dermal exposure studies conducted at three different laboratories. In all of these studies, the single common factor was that animals were housed individually. No such episodes have been observed in concurrent dosed feed, gavage, or drinking water studies in which rats from the same lineage were group housed. In the individually housed animals, most seizures were observed early in the day, when technical and maintenance activities were commencing following the animals' dark cycle period. No deaths were associated with seizures, and no correlations with body weight, diet, feed consumption, or histopathologic lesions were noted in this or other studies. These transient events were not considered to have affected the toxicologic or carcinogenicity evaluations of this 2-year study.

Data are presented as number of rats in a group with a clinical finding/the total number of rats in the group.
 Includes data for one female rat inadvertently removed from the study during week 21.

### Pathology and Statistical Analysis

This section describes the statistically significant or biologically noteworthy changes in the incidences of neoplasms and nonneoplastic lesions of the brain, skin, lung, eye, adrenal gland, lymph node, spleen, and urinary bladder. Summaries of the incidences of neoplasms and nonneoplastic lesions, individual animal tumor diagnoses, statistical analyses of primary neoplasms that occurred with an incidence of at least 5% in at least one animal group, and historical incidences for the neoplasms mentioned in this section are presented in Appendix A for male rats and Appendix B for female rats.

*Brain:* Neurological signs were exhibited by the 40 mg/kg males (Table 9). The principal pathological findings included neuronal necrosis, hemorrhage, and/or fibrinoid arteriole necrosis (Tables 10 and A5). Areas of neuronal necrosis were evident in 40 mg/kg males. Regions most frequently affected included frontal, cingulate and parietal cortex, basal ganglia and thalamus. This lesion was characterized by focal, usually bilateral, symmetrical presence of necrosis in regions of the cerebral cortex. Necrotic neurons were eosinophilic and shrunken (Plate 1) or were represented by "ghost forms" that were barely visible. The regions of neuronal necrosis were well defined, unaccompanied by reactive cells or hemorrhage. They were limited to specific cortical laminae, usually lamina 2 and 3 and surrounded by neurons that were well preserved. The severity of neuronal necrosis in affected foci was minimal to moderate, (one to five neurons affected) to an excess of 20 neurons affected.

Also present in the brain was fibrinoid necrosis of arteriole walls and parenchymal hemorrhage. Fibrinoid arteriole necrosis was characterized by a homogeneous, hyaline, eosinophilic deposit in the media and adventitia of affected arterioles and loss of nuclear detail of the vessel wall (Plate 2). Regions primarily affected with vascular lesions included frontal, cingulate, and parietal cortex, basal ganglia and dorsal thalamus. Fibrinoid arteriole necrosis was often focal but also in excess of six foci. Vascular lesions were sometimes accompanied by prominent fibrinous perivascular deposits that were more readily visible using Periodic Acid Schiff (PAS) staining. Many of the dosed animals examined using PAS staining had one or both of two arteriole lesions, fibrinoid arteriole necrosis or perivascular protein droplets (edema). These were characterized by focal, usually bilateral, symmetrical presence of fibrinoid arteriole necrosis and perivascular PAS positive proteinaceous droplets. Fibrinoid arteriole necrosis was characterized by expansion of the vascular walls by PAS positive fibrillar clumps in the media and adventitia (occasional venules and capillaries had similar lesions). The deposits in some cases were extensive enough to efface the morphology of the blood vessels. Distinct brightly PAS positive droplets 0.5 to 4 microns in diameter were apparent in Virchow-Robins spaces of arterioles that appeared to have no other demonstrable mural injury. Uncommonly, "lakes" of perivascular edema fluid, staining lightly PAS positive, were apparent in brain regions with fibrinoid arteriole necrosis. Evaluation of the acute cerebral hemorrhages showed that they correlated with the presence of fibrinoid arteriole necrosis using PAS staining. Parenchymal hemorrhages (Plate 3) were recent with no evidence of neutrophils, hemosiderin deposits or pigment phagocytosis. Hemorrhage commonly suffused the adventitia of the vessels in affected areas.

Skin (site of application): At the site of application, statistically significant increases in the incidences of epidermal hyperplasia occurred in all treated male groups and in 20 and 40 mg/kg females when compared to the vehicle controls (Tables 11, A5, and B4). Microscopically, this lesion of minimal severity was focal and characterized by a slight increase in thickness (two to three cell layers) of the squamous epithelium (Plate 4) when compared to controls (Plate 5). Significant increases in the incidences of chronic inflammation of minimal severity occurred in all treated male groups and 40 mg/kg females. Histologically, this lesion consisted of small numbers of mononuclear cells in the superficial dermis underlying lesions of epidermal hyperplasia (Plate 4).

<sup>\*</sup> Significantly different (P≤0.05) from the vehicle control group by the Poly-3 test

Lung: The incidence of hemorrhage in 40 mg/kg males was significantly increased when compared to the vehicle controls (Tables 12 and A5). The acute lesion was characterized by minimal to mild numbers of erythrocytes spread diffusely in alveolar spaces and in the perivascular adventitia of small blood vessels. Dark brown to black pigment consistent with hemosiderin in fixed macrophages around large and small bronchioles and pulmonary vessels indicated a chronic hemorrhagic lesion. Statistically significant increases occurred in the incidences of chronic inflammation in 10 and 20 mg/kg females and alveolar epithelium hyperplasia in 20 mg/kg females (Tables 12 and B4). Chronic inflammation consisted of minimal to mild perivascular infiltrates of lymphocytes, plasma cells, and macrophages. Alveolar epithelium hyperplasia was of minimal to mild severity and was characterized by increased numbers of cuboidal epithelial cells that lined alveoli.

Eye: A statistically significant increase in the incidence of corneal hyperplasia occurred in 40 mg/kg males (Tables 13 and A5). This lesion was of mild severity and was characterized by a slight increase in thickness of the corneal epithelium. Significantly increased incidences of chronic corneal inflammation of minimal severity occurred in 20 and 40 mg/kg males. Neovascularization of the corneal stroma with infiltration by variable numbers of inflammatory cells characterized this lesion.

Adrenal Gland (Medulla): The incidences of benign pheochromocytoma (vehicle control, 3/50; 10 mg/kg, 2/48, 20 mg/kg, 8/50; 40 mg/kg, 7/50) and benign, complex, or malignant pheochromocytoma (combined) (6/50, 6/48, 12/50, 9/50) occurred with positive trends in males. The incidences were not significantly different from the vehicle control group in any single dosed group and were within the historical control ranges [benign: 185/1,451 (12.8% to 6.0%), range 3% to 24%; benign, complex, or malignant (combined): 217/1,451 (15.1% ± 6.2%), range 5% to 28%] from 2-year NTP studies (Tables A3 and A4). The incidence of hyperplasia in 20 mg/kg males was significantly greater than that of the vehicle controls (7/50, 9/49, 16/50, 3/50; Table A5).

Other Organs: The incidences of hemorrhage in the mediastinal lymph node (2/18, 1/14, 4/16, 6/13), pigmentation in the spleen (9/50, 5/50, 6/50, 25/50), and chronic inflammation in the urinary bladder (0/50, 0/50, 2/50, 4/49) of 40 mg/kg males were significantly increased (Table A5).

# **MICE**

# 2-WEEK STUDY

No toxicity data were available on diisopropylcarbodiimide in the literature. Therefore, the high dose group in this study received 0.1 mL of neat diisopropylcarbodiimide (81 mg/animal). For the lower dose groups, diisopropylcarbodiimide was diluted with ethanol and administered at concentrations of 1, 3, 9, or 27 mg/animal; each animal received a total volume of 0.1 mL. The vehicle controls were administered 0.1 mL of ethanol only.

All 9, 27, and 81 mg males and females died before the end of the study (Table 14). Final body weights of the surviving groups were similar to those of the vehicle controls. Organ weights of 1 and 3 mg mice were generally similar to those of vehicle controls (Table G3). The dose levels selected for the 3-month studies were 0, 17.5, 35, 70, 140, or 280 mg/kg.

Day of death: 7, 7, 7, 8, 8

Bay of death: 1, 2, 2, 2, 2

# **3-MONTH STUDY**

All 280 mg/kg males and females and nine 140 mg/kg males and females died before the end of the study (Table 15). The final mean body weight gain of 70 mg/kg males was significantly less than that of the vehicle control group, the surviving 140 mg/kg male lost weight, and the final body weight of the surviving 140 mg/kg female was 77% that of the vehicle control group. Clinical findings observed in 140 and 280 mg/kg males and females included abnormal breathing, ataxia, comatose conditions, convulsions/seizures, irritation at the site of application, lethargy, ruffled fur, and thinness. No differences in the hematology parameters were observed (Table F2). Significant increases in absolute and relative kidney weights occurred in 17.5 and 35 mg/kg males; organ weights of the remaining groups were generally similar to those of the vehicle control groups (Table G4). Significant decreases in total spermatid heads per testis and average spermatid count occurred in 17.5 mg/kg males. No other significant differences in reproductive tissue parameters or estrous cycle characterization occurred (Tables H3 and H4).

Week of death: 4, 4, 4, 4, 5, 6, 6, 7, 7

d Week of death: 1

Week of death: 6, 6, 7, 7, 8, 9, 9, 10, 11 Week of death: 1, 1, 1, 2, 2, 2, 2, 2, 2, 2

At the site of application, the incidences of epidermal hyperplasia in males and females administered 70 mg/kg or greater, chronic inflammation in 140 and 280 mg/kg males and 70 mg/kg or greater females, and sebaceous gland hyperplasia in 140 mg/kg males were significantly increased (Table 16). Thymic atrophy was significantly increased in 140 and 280 mg/kg males and females.

Dose Selection Rationale: Based on mortality, body weight changes, and an increase in chronic active inflammation in females at the site of application at 70 mg/kg, 40 mg/kg per day was selected as the high dose for both sexes of B6C3F, mice in the 2-year study of diisopropylcarbodiimide.

Growth Curves for Male and Female Mice Administered
Diisopropylcarbodiimide Dermally for 2 Years

# Pathology and Statistical Findings

This section describes the statistically significant or biologically noteworthy changes in the incidences of neoplasms and nonneoplastic lesions of the lung, skin, and harderian gland. Summaries of the incidences of neoplasms and nonneoplastic lesions, individual animal tumor diagnoses, statistical analyses of primary neoplasms that occurred with an incidence of at least 5% in at least one animal group, and historical incidences for the neoplasms mentioned in this section are presented in in Appendix C for male mice and Appendix D for female mice.

Lung: The incidence of alveolar/bronchiolar carcinoma in 40 mg/kg females was significantly greater than that of the vehicle controls (vehicle control, 0/50; 10 mg/kg, 2/50; 20 mg/kg, 2/50; 40 mg/kg, 5/50); however, there was no treatment effect when alveolar/bronchiolar adenomas and carcinomas were combined (4/50, 4/50, 5/50, 6/50). The incidence of alveolar/bronchiolar carcinoma in 40 mg/kg females was within the historical control range (all routes: 40/1,552 (2.5%  $\pm$  2.6%), range 0% to 12%) (Tables D3 and D4).

Skin (site of application): Statistically significant increases in the incidences of minimal epidermal hyperplasia and focal inflammation of the dermis occurred in 20 mg/kg males when compared to the vehicle controls (Tables 20 and C4). Microscopically, epidermal hyperplasia was focal and characterized by a slight increase in the thickness of the squamous epithelium. Focal dermal inflammation consisted of small numbers of mononuclear cells in the superficial dermis underlying lesions of epidermal hyperplasia.

TABLE 20 Incidences of Selected Nonneoplastic Lesions of the Skin in Male Mice in the 2-Year Dermal Study of Diisopropylcarbodiimide

	Vehicle Control	10 mg/kg	20 mg/kg	40 mg/kg
Number Examined Microscopically Site of Application, Epidermis, Hyperplasia	50 2 (2.0) <sup>b</sup>	50 3 (2.3)	50 10* (1.8)	50 1 (1.0)
Site of Application, Dermis, Inflammation, Focal	2 (2.0)	2 (2.0)	9* (1.4)	1 (1.0)

<sup>\*</sup> Significantly different ( $P \le 0.05$ ) from the vehicle control group by the Poly-3 test

a Number of animals with lesion

Average severity grade of lesions in affected animals: 1=minimal, 2=mild, 3=moderate, 4=marked

*Harderian Gland:* There was a significant negative trend in the incidences of harderian gland adenoma in females, and the incidence in the 40 mg/kg group was significantly decreased when compared to vehicle controls (vehicle control, 9/50; 10 mg/kg, 5/50; 20 mg/kg, 5/50; 40 mg/kg, 3/50; Table D3). The incidence of this neoplasm in the vehicle controls was at the high end of the historical control range for all routes (122/1,558 (8.1%  $\pm$  5.8%), range 0% to 22%), and the decreased incidences in the dosed groups were not considered related to the administration of diisopropylcarbodiimide.

## GENETIC TOXICOLOGY

Diisopropylcarbodiimide was not mutagenic in Salmonella typhimurium strains TA97, TA98, TA100, or TA1535, with or without induced rat or hamster liver S9 activation enzymes (Table E1). Results of in vivo tests for chromosomal effects in mice and rats were discussed in detail by Witt et al. (1999) and data are presented in Tables E2 through E6. Diisopropylcarbodiimide, administered dermally for 3 months, induced significant increases in the frequency of micronucleated normochromatic erythrocytes (NCEs) in peripheral blood of male and female mice (Table E5). The percent polychromatic erythrocytes (PCEs) in these mice was unaffected by chemical treatment. Negative results were obtained in a subsequent acute exposure bone marrow micronucleus test in male F344/N rats using an intraperitoneal injection route of chemical administration at doses that produced clear evidence of bone marrow toxicity based on decreases in percent PCEs (Table E2). Diisopropylcarbodiimide was then tested for induction of micronucleated PCEs in male B6C3F<sub>1</sub> mice, the same strain employed in the 3-month dermal study, and the results of this test, assaying the frequency of micronucleated PCEs in bone marrow, were negative (Table E3). The values of percent PCEs in this mouse study were unchanged with increasing dose, even though chemical-related toxicity was noted at the two highest doses tested. To permit the administration of a higher dose of diisopropylcarbodiimide in mice and to allow scoring of both blood and bone marrow erythrocytes in the same animals, single injection micronucleus studies were conducted with sampling at 24 and 48 hours posttreatment. Micronucleated erythrocytes were significantly increased in peripheral blood PCEs at 48 hours in both trials, but bone marrow smears showed increases in micronucleated PCEs that were not statistically significant at 24 or 48 hours (Table E4). As seen in the acute rat bone marrow study, the percent of PCEs in the bone marrow of mice in Trial 1 was significantly depressed. To clarify the mixed responses in the acute and subchronic tests, a second dermal study of diisopropylcarbodiimide in male mice was performed. Analysis of the mean frequencies of micronucleated PCEs and NCEs in peripheral blood, derived from the pooling of data from interim samplings over the 4-month course of treatment, showed highly significant increases (Table E6). The frequency of micronucleated PCEs in the bone marrow of treated mice on day 124 (final day of treatment) was not significantly increased over the solvent control level. The percent PCEs were not significantly altered at any of the sample times in either bone marrow or peripheral blood in the 4-month dermal study (data not shown; Witt *et al.*, 1999).

PLATE 1 Area of neuronal necrosis in the brain of a male rat dermally administered 40 mg/kg diisopropylcarbodiimide for 2 years. Note normal neuron (arrowhead) surrounded by shrunken, eosinophilic necrotic neurons (arrows). H&E;  $40\times$ 

PLATE 3 Hemorrhage (arrows) in the brain of a male rat dermally administered 40 mg/kg diisopropylcarbodiimide for 2 years. H&E;  $20^{\times}$ 

**PLATE 2** Fibrinoid arteriole necrosis in the brain of a male rat dermally administered 40 mg/kg diisopropylcarbodiimide for 2 years. Note the thickening of the arteriole wall by homogeneous, hyaline, eosinophilic deposits with loss of nuclear detail (arrow). H&E;  $40\times$ 

PLATE 4 Epidermal hyperplasia and chronic inflammation of minimal severity in the skin of a male rat dermally administered 40 mg/kg diisopropylcarbodiimide for 2 years. Note the increased thickness of the squamous epithelium (arrow) and the focal infiltration of mononuclear cells in the superficial dermis (arrowhead) when compared to skin of a vehicle control rat (Plate 5). H&E;  $16\times$ 

PLATE 5
Skin of a vehicle control male rat from the 2-year dermal study of diisopropylcarbodiimide. Note the normal thickness (one to two cell layers) of the squamous epithelium (arrow). H&E;  $16\times$ 

## **DISCUSSION AND CONCLUSIONS**

Diisopropylcarbodiimide and dicyclohexylcarbodiimide were studied by the NTP as representatives of the carbodiimide class of chemicals. The results of the dicyclohexylcarbodiimide studies will be reported separately.

Only one diisopropylcarbodiimide oral acute toxicity study in mice was found in the literature. The studies reported here show that rats are more sensitive to the toxic effects of diisopropylcarbodiimide than mice. The major organs of toxicity were identified as skin at the site of application and the central nervous system in both rats and mice, and lung toxicity was observed in rats.

Dose-related increases in inflammation and hyperplasia of the skin at the site of application were observed in the 2-week, 3-month, and 2-year studies in rats and mice, with the severity of lesions generally more pronounced in rats. Inflammation of the eye and corneal hyperplasia were observed only in rats in the 2-year studies. These results are consistent with previously published results demonstrating the irritant capacity of the chemical. Diisopropylcarbodiimide has been shown to be both a skin and eye irritant in humans after occupational exposure (Moyer, 1990; Hayes *et al.*, 1998).

The disposition studies conducted by the NTP in rats and mice using the dermal route of exposure showed that diisopropylcarbodiimide is not readily absorbed (Appendix L). Only small percentages of the radiolabeled diisopropylcarbodiimide, ranging from 1.1% to 6.6% in rats and about 2.3% in mice, were absorbed. The majority of the dosing material applied at the site of application appeared to have been volatilized and was not available for absorption. The tissues analyzed for distribution had minimal levels of diisopropylcarbodiimide and, in some experiments, the tissue:blood ratio could not be determined because the measured radioactivity in blood was not significantly different from the background level. These studies suggest that animals in the current dermal studies

were also exposed by inhalation to diisopropylcarbodiimide vapors emitted from the site of application that was not occluded. The central nervous system toxicity and lung effects observed were considered due to systemic absorption of the chemical by inhalation as well as by oral ingestion (grooming) rather than dermal exposure alone.

The central nervous system was adversely affected by diisopropylcarbodiimide exposure in both rats and mice. There were species and sex differences in expression of the clinical signs of central nervous system toxicity. The clinical signs of neurotoxicity such as ataxia, seizures, excitability, hyperactivity, impaired gait, and low muscle tone occurred in rats and mice in the 2-week and 3-month studies but only in rats during the 2-year studies. Male rats displayed more severe and more frequent signs of central nervous system toxicity than females. Some of the 40 mg/kg male rats in the 2-year studies reacted to skin touch by displaying violent spasms and vocalization expressive of pain. These clinical signs of toxicity were accompanied with pathological findings in the brain. Lesions in the brain included neuronal necrosis, cerebral hemorrhage, and/or fibrinoid arteriole necrosis. The phenomenon of generalized pain as a result of brain injury has been well described in the literature, and includes a steady painful sensation that is increased significantly by light touch (Xu et al., 1992; Beric, 1998; Vespa et al., 2003; Nicholson, 2004). It is possible that the reaction to stimuli observed in 40 mg/kg males in the current study is due to a similar phenomenon resulting from brain and spinal cord injury.

Lung congestion in the 3-month studies and dose-related increases in the incidences of hemorrhage in the 2-year studies were observed in rats only. The hemorrhage in the male rat lung was characterized by minimal to mild numbers of erythrocytes spread diffusely in alveolar spaces and in the perivascular adventitia of small blood vessels. The presence of acute hemorrhage and dark brown to black pigment in fixed macrophages around large and small bronchioles and pulmonary vessels suggests ongoing and prior events. These findings, combined with the incidences of fibroid arteriole necrosis in 40 mg/kg male rat brains suggest the blood vessel is a target of diisopropylcarbodiimide.

It is well established that inhibition of cell membrane ATPase interferes with the normal function of cell membrane by impairment of the Na<sup>+</sup>-K<sup>+</sup> pump. Also, it is proposed that inhibition of sodium-potassium-ATPase is a potentially ubiquitous mechanism contributing to central nervous system neuropathy (Lees, 1991). Diisopropylcarbodiimide is shown to inactivate ATPase in *Escherichia coli* (Satre *et al.*, 1979). It is possible the neurotoxicity observed in these studies is due to inhibition of ATPase by diisopropylcarbodiimide.

No carcinogenic activity was identified in the current studies that was related to diisopropylcarbodiimide exposure in rats or mice. Data from the NTP diisopropylcarbodiimide study with the p53 haploinsufficient mouse model also show no carcinogenic effects related to diisopropylcarbodiimide treatment (NTP, 2005).

Diisopropylcarbodiimide is not mutagenic in the Salmonella assay, but results of a series of in vivo mutagenicity tests showed clear evidence of increased micronucleus frequencies in the blood of male and female mice following three or more months of exposure via skin painting (Witt et al., 1999). In contrast, results of intraperitoneal injection as the route of exposure were negative, and no increase in micronucleus frequency was seen in male mouse bone marrow following the 4-month skin painting exposure. Results of a single intraperitoneal injection mouse micronucleus test showed significant increases in micronucleated polychromatic erythrocytes in peripheral blood 48 hours after dosing, but results were negative in bone marrow. Together, these data suggest that diisopropylcarbodiimide may target the spleen, thereby producing elevated frequencies of micronucleated erythrocytes in blood but not bone marrow. The results of the peripheral blood micronucleus tests are somewhat surprising because a strong correlation has been reported between positive results in subchronic peripheral blood micronucleus tests and rodent carcinogenicity (Witt et al., 2000). The database from which this correlation derives is small, although additional support for the relationship between positive rodent micronucleus test data and carcinogenicity was provided by Morita et al. (1997) as well as the Environmental Protection Agency (EPA) Gene-Tox program, which estimated that 70% of EPA-identified carcinogens would be detected in appropriatelydesigned micronucleus assays (Heddle et al., 1983). The pattern of activity shown by diisopropylcarbodiimide is unusual.

## **CONCLUSIONS**

Under the conditions of these 2-year dermal studies, there was no evidence of carcinogenic activity\* of disopropylcarbodiimide in male or female F344/N rats or B6C3F $_1$  mice administered 10, 20, or 40 mg/kg.

Diisopropylcarbodiimide was associated with clinical signs of neurotoxicity and with brain hemorrhage in male rats.

<sup>\*</sup> Explanation of Levels of Evidence of Carcinogenic Activity is on page 13.

•				

<sup>(</sup>T) Terminal sacrifice

a Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland,

pancreas, pancreatic islets, pituitary gland, preputial gland, testes, and thyroid gland; for other tissues, denominator is number of animals necropsied.

Poly-3 estimated neoplasm incidence after adjustment for intercurrent mortality

Observed incidence at terminal kill

Beneath the vehicle control incidence is the P value associated with the trend test. Beneath the dosed group incidence is the P value corresponding to pairwise comparisons between the vehicle controls and that dosed group. The Poly-3 test accounts for the differential mortality in animals that do not reach terminal sacrifice. A negative trend or a lower incidence in a dosed group is indicated by N.

Not applicable; no neoplasms in animal group

Value of statistic cannot be computed

TABLE A4
Historical Incidence of Adrenal Gland Pheochromocytoma in Control Male F344/N Rats<sup>a</sup>

## (T) Terminal sacrifice

Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, clitoral gland, liver, pituitary gland, and thyroid gland; for other tissues, denominator is number of animals necropsied.

Poly-3 estimated neoplasm incidence after adjustment for intercurrent mortality

Observed incidence at terminal kill

Beneath the vehicle control incidence is the P value associated with the trend test. Beneath the dosed group incidence is the P value corresponding to pairwise comparisons between the vehicle controls and that dosed group. The Poly-3 test accounts for the differential mortality in animals that do not reach terminal sacrifice. A negative trend or a lower incidence in a dosed group is indicated by N.

Not applicable; no neoplasms in animal group

Value of statistic cannot be computed

<sup>(</sup>T)Terminal sacrifice

Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, liver, and lung; for other tissues, denominator is number of animals necropsied.

Poly-3 estimated neoplasm incidence after adjustment for intercurrent mortality

Observed incidence at terminal kill

Beneath the vehicle control incidence is the P value associated with the trend test. Beneath the dosed group incidence is the P value corresponding to pairwise comparisons between the vehicle controls and that of the dosed group. The Poly-3 test accounts for the differential mortality in animals that do not reach terminal sacrifice. A negative trend or a lower incidence in a dosed group is indicated by N.

Not applicable; no neoplasms in animal group

Value of statistic cannot be computed.

One hepatoblastoma occurred in an animal that also had an adenoma

<sup>(</sup>T)Terminal sacrifice

Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for liver, lung, pituitary gland, and thyroid gland; for other tissues, denominator is number of animals necropsied.

Poly-3 estimated neoplasm incidence after adjustment for intercurrent mortality

Observed incidence at terminal kill

Beneath the vehicle control group is the P value associated with the trend test. Beneath the dosed group incidence is the P value corresponding to pairwise comparisons between the vehicle controls and that of the dosed group. The Poly-3 test accounts for the differential mortality in animals that do not reach terminal sacrifice. A negative trend or a lower incidence in a dosed group is indicated by N.

Not applicable; no neoplasms in animal group

Value of statistic could not be computed

g One stromal sarcoma occurred in an animal that also had a stromal polyp

## **GENETIC TOXICOLOGY**

#### SALMONELLA TYPHIMURIUM MUTAGENICITY TEST PROTOCOL

Testing was performed as reported by Zeiger *et al.* (1992). Diisopropylcarbodiimide was sent to the laboratory as a coded aliquot from Radian Corporation (Austin, TX). It was incubated with the *Salmonella typhimurium* tester strains TA97, TA98, TA100, and TA1535 either in buffer or S9 mix (metabolic activation enzymes and cofactors from Aroclor 1254-induced male Sprague-Dawley rat or Syrian hamster liver) for 20 minutes at 37° C. Top agar supplemented with L-histidine and d-biotin was added, and the contents of the tubes were mixed and poured onto the surfaces of minimal glucose agar plates. Histidine-independent mutant colonies arising on these plates were counted following incubation for 2 days at 37° C.

Each trial consisted of triplicate plates of concurrent positive and negative controls and five doses of disopropylcarbodiimide. The high dose was limited by toxicity. Trials were generally repeated at the same or a higher S9 fraction.

In this assay, a positive response is defined as a reproducible, dose-related increase in histidine-independent (revertant) colonies in any one strain/activation combination. An equivocal response is defined as an increase in revertants that is not dose related, is not reproducible, or is not of sufficient magnitude to support a determination of mutagenicity. A negative response is obtained when no increase in revertant colonies is observed following chemical treatment. There is no minimum percentage or fold increase required for a chemical to be judged positive or weakly positive.

### RAT AND MOUSE BONE MARROW MICRONUCLEUS TEST PROTOCOLS

The detailed protocols are described by Witt *et al.* (1999). Information from the 3-month dermal studies with diisopropylcarbodiimide was used to select the range of doses in these studies. Bone marrow tests were initially performed using the standard three-exposure protocol described in detail by Shelby *et al.* (1993). Male F344/N rats and B6C3F<sub>1</sub> mice were injected intraperitoneally (three times at 24-hour intervals) with diisopropylcarbodiimide dissolved in corn oil. Vehicle control animals were injected with corn oil only. The positive control animals received injections of cyclophosphamide. The animals were killed 24 hours after the third injection, and blood smears were prepared from bone marrow cells obtained from the femurs.

Single injection bone marrow micronucleus tests were conducted with diisopropylcarbodiimide in B6C3F<sub>1</sub> male mice. These studies were designed to permit the testing of higher doses than could be administered in the multiple treatment protocol described above. The positive control was again cyclophosphamide. Two different posttreatment samples were collected; peripheral blood smears were prepared 48 hours after injection and bone marrow slides were prepared 24 and 48 hours after injection.

A subchronic micronucleus test was performed in which  $B6C3F_1$  mice were treated 5 days per week for 4 months with disopropylcarbodiimide dissolved in ethanol; the treatment protocol was designed to match the treatment protocol employed in the 3-month dermal study. At the end of the study, bone marrow cells were obtained and slides were prepared.

Air-dried smears from all the bone marrow micronucleus tests were fixed in absolute methanol and stained with acridine orange (Tice *et al.*, 1990); 2,000 PCEs were scored per animal for frequency of micronucleated cells in blood, bone marrow, or both from up to five animals per group. In addition, the percentage of PCEs among the total erythrocyte population in the bone marrow was scored for each dose group as a measure of toxicity.

The results of the bone marrow tests were tabulated as the mean of the pooled results from all animals within a treatment group, plus or minus the standard error of the mean. The frequency of micronucleated cells among PCEs

was analyzed by a statistical software package that tested for increasing trend over dose or exposure groups using a one-tailed Cochran-Armitage trend test, followed by pairwise comparisons between each dose or exposure group and the control group (ILS, 1990). In the presence of excess binomial variation, as detected by a binomial dispersion test, the binomial variance of the Cochran-Armitage test was adjusted upward in proportion to the excess variation. In the micronucleus test, an individual trial is considered positive if the trend test P value is less than or equal to 0.025 or the P value for any single dosed or exposed group is less than or equal to 0.025 divided by the number of dosed or exposed groups. A final call of positive for micronucleus induction is preferably based on reproducibly positive trials (as noted above). Ultimately, the final call is determined by the scientific staff after considering the results of statistical analyses, reproducibility of any effects observed, and the magnitudes of those effects.

### MOUSE PERIPHERAL BLOOD MICRONUCLEUS TEST PROTOCOL

A detailed discussion of the testing protocol was presented by Witt *et al.* (1999). At the termination of the 3-month dermal study, blood samples were obtained from male and female mice. Smears were immediately prepared and fixed in absolute methanol. The methanol-fixed slides were stained with acridine orange and coded. Slides were scanned to determine the frequency of micronuclei in 1,000 normochromatic erythrocytes (NCEs) in up to 10 mice per dose group. In addition, the percentage of PCEs among 1,000 erythrocytes was determined for each dose group.

In the single injection study in male mice described for the bone marrow micronucleus tests, peripheral blood samples were obtained from the animals killed 48 hours after the injection, and smears were air-dried, fixed, and analyzed for micronucleated PCEs and percentage of PCEs among the total erythrocyte population.

During the 4-month dermal study, periodic blood samples (weekly through week 7, biweekly thereafter, and at the end of the study on dosing day 124) were taken from each mouse via tail snip. Samples were collected within 24 hours of the last of at least three consecutive daily treatments with diisopropylcarbodiimide. Peripheral blood slides were made for analysis of the frequency of micronuclei in 2,000 PCEs and 2,000 NCEs, and for scoring the percentage of PCEs in the total erythrocyte population in the peripheral blood in each of five animals per group.

The results of the peripheral blood tests were tabulated and the frequencies of micronucleated cells among PCEs and NCEs were analyzed as described for PCEs in the bone marrow micronucleus test protocols. Results for the 3-and 4-month studies were accepted without repeat tests, because additional test data could not be obtained.

#### **EVALUATION PROTOCOL**

These are the basic guidelines for arriving at an overall assay result for assays performed by the National Toxicology Program. Statistical as well as biological factors are considered. For an individual assay, the statistical procedures for data analysis have been described in the preceding protocols. There have been instances, however, in which multiple aliquots of a chemical were tested in the same assay, and different results were obtained among aliquots and/or among laboratories. Results from more than one aliquot or from more than one laboratory are not simply combined into an overall result. Rather, all the data are critically evaluated, particularly with regard to pertinent protocol variations, in determining the weight of evidence for an overall conclusion of chemical activity in an assay. In addition to multiple aliquots, the *in vitro* assays have another variable that must be considered in arriving at an overall test result. *In vitro* assays are conducted with and without exogenous metabolic activation. Results obtained in the absence of activation are not combined with results obtained in the presence of activation; each testing condition is evaluated separately. The Summary Table in the Abstract of this Technical Report presents a result that represents a scientific judgment of the overall evidence for activity of the chemical in an assay.

#### RESULTS

Diisopropylcarbodiimide was not mutagenic in S. typhimurium strains TA97, TA98, TA100, or TA1535, with or without induced rat or hamster liver S9 activation enzymes (Table E1). Results of in vivo tests for chromosomal effects in mice and rats were discussed in detail by Witt et al. (1999) and the data are presented in Tables E2 through E6. Diisopropylcarbodiimide, administered dermally for 3 months, induced significant increases in the frequency of micronucleated NCEs in peripheral blood of male and female mice (Table E5). The percent PCEs in these mice was unaffected by chemical treatment. Negative results were obtained in a subsequent acute exposure bone marrow micronucleus test in male F344/N rats using an intraperitoneal injection route of chemical administration at doses that produced clear evidence of bone marrow toxicity based on decreases in percent PCEs (Table E2). Diisopropylcarbodiimide was then tested for induction of micronucleated PCEs in male B6C3F<sub>1</sub> mice, the same strain employed in the 3-month dermal study, and the results of this test, assaying the frequency of micronucleated PCEs in bone marrow, were negative (Table E3). The values of percent PCEs in this mouse study were unchanged with increasing dose, even though chemical-related toxicity was noted at the two highest doses tested. To permit the administration of a higher dose of diisopropylcarbodiimide in mice and to allow scoring of both blood and bone marrow erythrocytes in the same animals, single injection micronucleus studies were conducted with sampling at 24 and 48 hours posttreatment. Micronucleated erythrocytes were significantly increased in peripheral blood PCEs at 48 hours in both trials, but bone marrow smears showed increases in micronucleated PCEs that were not statistically significant at 24 or 48 hours (Table E4). As seen in the acute rat bone marrow study, the percent of PCEs in the bone marrow of mice in Trial 1 was significantly depressed. To clarify the mixed responses in the acute and subchronic tests, a second dermal study of diisopropylcarbodiimide in male mice was performed. Analysis of the mean frequencies of micronucleated PCEs and NCEs in peripheral blood, derived from the pooling of data from interim samplings over the 4-month course of treatment, showed highly significant increases (Table E6). The frequency of micronucleated PCEs in the bone marrow of treated mice on day 124 (final day of treatment) was not significantly increased over the solvent control level. The percent PCEs were not significantly altered at any of the sample times in either bone marrow or peripheral blood in the 4-month dermal study (data not shown; Witt et al., 1999).

<sup>&</sup>lt;sup>a</sup> Study was performed at SRI International. The detailed protocol is presented by Zeiger *et al.* (1992). 0 µg/plate was the solvent control.

b Revertants are presented as mean  $\pm$  standard error from three plates.

c Slight toxicity

The positive controls in the absence of metabolic activation were sodium azide (TA100 and TA1535), 9-aminoacridine (TA97), and 4-nitro-o-phenylenediamine (TA98). The positive control for metabolic activation with all strains was 2-aminoanthracene.

### CHEMICAL CHARACTERIZATION AND DOSE FORMULATION STUDIES

#### PROCUREMENT AND CHARACTERIZATION

#### Diisopropylcarbodiimide

Diisopropylcarbodiimide was obtained from Aldrich Chemical Company (Milwaukee, WI) in three lots. Lot 01207BG was used during the 2-week and 3-month studies; lot 13016JS was used during the 2-year studies. One additional lot (09330DR) was used solely for dose formulation stability studies and was not used in the animal studies. Identity and purity analyses were conducted by the analytical chemistry laboratory at Midwest Research Institute (Kansas City, MO) and by the study laboratories at Microbiological Associates, Inc. (Bethesda, MD; 2-week and 3-month studies), and Southern Research Institute (Birmingham, AL; 2-year studies); physical properties, moisture content, and stability of the bulk diisopropylcarbodiimide were determined by the analytical chemistry laboratory. Reports on analyses performed in support of the diisopropylcarbodiimide studies are on file at the National Institute of Environmental Health Sciences.

Lot 01207BG, a colorless liquid, was identified as diisopropylcarbodiimide by the study laboratory using infrared (IR) spectroscopy. Lot 13016JS was identified as diisopropylcarbodiimide by the study laboratory using IR and proton nuclear magnetic resonance (NMR) spectroscopy and by the analytical chemistry laboratory using IR, proton NMR, and ultraviolet/visible spectroscopy and gas chromatography (GC)/mass spectrometry by system A (Table I1). All spectra were consistent with the structure of diisopropylcarbodiimide and with literature references (*Aldrich* 1981, 1985, 1993. Representative IR and proton NMR spectra are presented in Figures I1 and I2.

The purity of lot 01207BG was determined by the study laboratory using GC system B. The purity of lot 13016JS was determined by the study laboratory using GC system C and by the analytical chemistry laboratory using thin layer chromatography (TLC) and GC system D. The moisture content of lot 13016JS was determined by the analytical chemistry laboratory using Karl Fischer titration; the boiling point and relative density of this lot were also measured by the analytical chemistry laboratory.

For lot 01207BG, GC by system B indicated a major peak and five impurity peaks with areas ranging from 0.05% to 0.27% of the total peak area. Fourteen minor impurities were present in the sample chromatograms. The overall purity of lot 01207BG was determined to be 99.35%.

For lot 13016JS, the boiling point (147.2° C) and relative density (0.813 at 25° C) were consistent with the literature values for diisopropylcarbodiimide (*Aldrich*, 1985). Karl Fischer titration indicated 0.06% water in the bulk chemical. TLC detected a major, a minor, and two trace spots. GC by system C indicated a relative purity of 102% when compared to a frozen reference sample from the analytical chemistry laboratory and a mean purity of 99.6% when calculated on an area percent. GC by system D indicated a major peak and five impurity peaks with a combined area of approximately 0.5% of the total peak area; the purity of the test article was determined to be approximately 99.5%. The overall purity of lot 13016JS was determined to be greater than 99%.

The analytical chemistry laboratory conducted accelerated stability studies of lot 13016JS with samples stored for 2 weeks in amber vials with Teflon®-lined septa at approximately 5°, 25°, and 60° C compared to frozen samples from the same lot stored at -20° C. Analysis using GC system E indicated that the test article was stable when protected from light at temperatures up to approximately 60° C for at least 2 weeks. To ensure stability, the bulk chemical was stored at room temperature under nitrogen, protected from light as recommended by the manufacturer. Stability was monitored by the study laboratories during the 3-month and 2-year studies using GC systems B and C, respectively; no degradation of the bulk chemical was detected.

#### **Anhydrous Ethanol**

Anhydrous ethanol was obtained in two lots (09115LU and 09309PI) from Aldrich Chemical Company for use during the 2-year studies. Identity and purity analyses of both lots were conducted by the study laboratory. The chemical, a clear liquid, was identified as ethanol using IR spectroscopy; the sample spectra were a good match for the reference spectrum of ethanol (*Aldrich*, 1985). The purity of each lot was determined using GC by system F. No impurities were detected that exceeded a relative concentration of 0.1% in either lot.

To ensure stability, the bulk chemical was stored at room temperature. Purity reanalyses were performed by the study laboratory at approximately 6-month intervals during the 2-year study and no degradation of the ethanol was detected.

#### PREPARATION AND ANALYSIS OF DOSE FORMULATIONS

Except for the 242 mg (rats) and 81 mg (mice) dose formulations, which were used neat in the 2-week studies, the dose formulations were prepared by mixing diisopropylcarbodiimide and anhydrous ethanol to give the required concentrations; formulations were prepared once for the 2-week studies and weekly, biweekly, or monthly for the 3-month and 2-year studies (Table I2). The dose formulations were stored at room temperature (2-week and 3-month studies) or refrigerated (2-year studies) for up to 28 days.

Because the dose formulations were the neat test article or true solutions of the test article in ethanol, homogeneity studies were not performed. A stability study of a 10 mg/mL dose formulation of lot 01207BG was conducted by the study laboratory using GC by system G; stability was confirmed for at least 28 days for the dose formulation stored at ambient temperature in sealed containers. In a subsequent 35-day dose formulation stability study of lot 09330DR (not used in the animal studies), the analytical chemistry laboratory utilized GC by system H to determine that a 2 mg/mL dose formulation was stable for at least 21 days when stored refrigerated in sealed glass containers and for up to 3 hours when exposed to light at ambient temperature. The study laboratory conducted a stability study of 5.0 and 20.0 mg/mL dose formulations of lot 13016JS and determined that the formulations were stable for at least 35 days when stored refrigerated in sealed glass containers.

Periodic analyses of the dose formulations of diisopropylcarbodiimide were conducted by the study laboratories using GC by systems G (2-week and 3-month studies) and C (2-year studies). During the 2-week studies, the dose formulations were analyzed once; all five dose formulations for rats and mice were within 10% of the target concentrations (Table I3). Animal room samples of these dose formulations were also analyzed; all five of the animal room samples for rats and mice were within 10% of the target concentrations. Dose formulations were analyzed at the beginning, midpoint, and end of the 3-month studies; animal room samples of these dose formulations were also analyzed (Table I4). Of the dose formulations analyzed, all 14 for rats and 13 for mice were within 10% of the target concentrations; all 12 and 13 of the animal room samples for rats and mice, respectively, were within 10% of the target concentrations. During the 2-year studies, the dose formulations were generally analyzed every 8 to 12 weeks; animal room samples of these dose formulations were also analyzed (Table I5). All 33 of the dose formulations analyzed and used for rats and mice were within 10% of the target concentrations. Of the animal room samples analyzed, 92% (11/12) of those for rats and 83% (10/12) of those for mice were within 10% of the target concentrations.

Flame ionization	Rtx-5, 30 m $\times$ 0.53 mm, 1.0 $\mu$ m (Restek)	Helium at 10 mL/minute	70° C isothermal
System F			
Flame ionization	SPB-1, 30 m $\times$ 0.53 mm, 1.0 $\mu$ m (Supelco, Inc., Bellefonte, PA)	Helium at 8 mL/minute	40° C, held for 4 minutes, then 10° C/minute to 220° C
System G			
Flame ionization	J&W DB-1, 30 m × 0.53 mm, 3 μm (J&W Scientific)	Nitrogen at 17.5 mL/minute	115° C isothermal
System H			
Flame ionization	DB-5, 30 m $\times$ 0.53 mm, 1.5 $\mu$ m (J&W Scientific)	Helium at 10 mL/minute	50° C, held for 6 minutes, then 15° C/minute to 250° C, held for 3 minutes

<sup>&</sup>lt;sup>a</sup> Gas chromatographs manufactured by Thermo Electron Corp. (Finnigan), San Jose, CA (A), Hewlett-Packard, Palo Alto, CA (B, C, F, G), Varian, Palo Alto, CA (systems D, E, H); mass spectrometer was manufactured by Finnigan.

TABLE I2
Preparation and Storage of Dose Formulations in the Dermal Studies of Diisopropylcarbodiimide

2-Week Studies	3-Month Studies	2-Year Studies
Preparation The highest dose of diisopropylcarbodiimide was administered as the neat liquid. The next highest dose concentration was prepared by diluting a weighed amount of the test chemical in anhydrous ethanol; aliquots of this solution were diluted with additional anhydrous ethanol to obtain formulations of the three lower concentrations. Dose formulations were prepared once.	The most concentrated dose formulation for each species was prepared by diluting a weighed amount of the test chemical in anhydrous ethanol; aliquots of these solutions were diluted with additional anhydrous ethanol to obtain formulations of the four lower concentrations. Dose formulations for the rat study were prepared weekly for 4 weeks and at 2-week intervals thereafter; for the mouse study, dose formulations were prepared at 2-week intervals throughout.	A weighed amount of the test chemical was diluted with anhydrous ethanol to obtain each desired concentration for the dose formulations. Dose formulations were prepared weekly for 2 weeks (rats only), biweekly until June 26, 2000, and monthly thereafter.

### SENTINEL ANIMAL PROGRAM

#### **Methods**

Rodents used in the Carcinogenesis Program of the National Toxicology Program are produced in optimally clean facilities to eliminate potential pathogens that may affect study results. The Sentinel Animal Program is part of the periodic monitoring of animal health that occurs during the toxicologic evaluation of chemical compounds. Under this program, the disease state of the rodents is monitored via serology on sera from extra (sentinel) animals in the study rooms. These animals and the study animals are subject to identical environmental conditions. The sentinel animals come from the same production source and weanling groups as the animals used for the studies of chemical compounds.

Serum samples were collected from five male and five female control rats and mice at the end of the 3-month study. For the 2-year studies, serum samples were collected from five male and five female sentinel rats and mice at 6, 12, and 18 months and five 40 mg/kg males and females at study termination. Blood from each animal was collected and allowed to clot, and the serum was separated. The samples were processed appropriately and sent to Microbiological Associates, Inc. (Rockville, MD), or BioReliance Corp. (Rockville, MD) for determination of antibody titers. The laboratory serology methods and viral agents for which testing was performed are tabulated below; the times at which blood was collected during the studies are also listed.

# ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

#### Introduction

Because toxicity testing has shown diisopropylcarbodiimide to be very toxic (Microbiological Associates, 1995), the objectives of these studies were to determine the absorption and rates and routes of excretion of radiolabeled compounds following dermal exposure to [14C]-diisopropylcarbodiimide, and determine the rates and routes of excretion of radiolabeled compounds and the time course of radioactivity in blood following intravenous injection of [14C]-diisopropylcarbodiimide.

#### MATERIALS AND METHODS

Young adult male Fischer 344/N rats and B6C3F<sub>1</sub> mice were obtained from Charles River Laboratories (Raleigh, NC). Animals were quarantined for at least 1 week prior to being used in a study. Animals used for excreta collection were acclimated to metabolism chambers 1 day prior to dosing. Animals were fed certified Purina Rodent Chow (#5002; Ralston Purina Co., St. Louis, MO) and furnished tap water *ad libitum*. Prior to study initiation, animals were housed in polycarbonate cages. Contact bedding was Sani-Chips<sup>®</sup> (P.J. Murphy Forest Products Corp., Montville, NJ). During metabolism studies, animals were housed individually in all-glass, Roth-type metabolism chambers which provided for separate collection of urine and feces. Air circulation was 100% fresh filtered air with 10 to 15 air changes per hour and no interchange of air between rooms. Room temperature was maintained at 64° to 79° F, and relative humidity ranged from 30% to 70%. Light/darkness was cycled at 12-hour intervals. Each dose group contained at least three study animals.

Anesthesia was used to avoid undue pain or distress. Rats were anesthetized with an intramuscular injection of ketamine:xylazine (7:1, approximately 60 mg/kg or to effect). Mice were anesthetized with an intraperitoneal injection of sodium pentobarbital (60 mg/kg or to effect). Anesthetized rats were euthanized by cutting the diaphragm after final blood collection or by CO<sub>2</sub> asphyxiation at the end of the study. Anesthetized mice were euthanized by cervical dislocation, cutting the diaphragm, or CO<sub>2</sub> asphyxiation after final blood collection.

For dermal studies in rats, nonocclusive protective appliances were prepared from charcoal-impregnated filters. A circular template with an inner diameter of approximately 7 cm and an outer diameter of approximately 8 cm was transferred to a charcoal filter. A gathering stitch was sewn at the inner diameter mark with a second row of tighter stitches applied at the outer diameter mark. When drawn together, the inner gathering stitches formed a blister-shaped appliance with a flat edge that was used to glue the appliance onto the rat's back using Duro<sup>®</sup> Quick Gel<sup>®</sup>. A ring of Teflon<sup>®</sup> tubing was used to reinforce the inside top of the appliance, and keep the appliance off the dose application site. A metal protective shield was also placed over the appliance and attached to the animal using Duro<sup>®</sup> Quick Gel<sup>®</sup> and an Elastoplast<sup>®</sup> adhesive bandage.

For dermal studies in mice, the protective appliance was a wire mesh tissue capsule (Shandon-Lipshaw, Philadelphia, PA) covered by a charcoal-impregnated filter (3M® Company, St. Paul, MN). A metal protective shield was also placed over the capsule and attached to the animal using Duro® Quick Gel® and an Elastoplast® adhesive bandage.

Approximately 24 hours prior to dermal dose administration, animals were anesthetized and the fur on their backs was removed with a No. 40 animal clipper (Oster® Professional Products). The clipped area was washed with soapy water, rinsed with water, and dried. The clipped area was examined for nicks or breaks in the skin. Any animals with broken skin in the clipped area were excluded. For rats, a dose site of approximately 12 cm² was inscribed within the clipped area using a permanent felt-tip marker. For mice, a dose site of approximately 3 cm² was inscribed. A protective appliance, previously described, was attached to the back of each animal.

Nonradiolabeled diisopropylcarbodiimide (purity 99%), lot EN08119EN, was obtained from Aldrich Chemical Company (Milwaukee, WI). The identity of the nonradiolabeled diisopropylcarbodiimide was confirmed by nuclear magnetic resonance spectroscopy (NMR) and gas chromatography/mass spectrometry. Diisopropylcarbodiimide, labeled with <sup>14</sup>C in the 2-propyl position (20 mCi/mmol, 10 mCi), was received from Wizard Laboratories, Inc. (West Sacramento, CA), at a stated radiochemical purity of 98.7% (by thin layer chromatography).

\* Position of 14C

#### Structure of [14C]-Diisopropylcarbodiimide

The radiochemical purity of [ $^{14}$ C]-diisopropylcarbodiimide was initially estimated at Research Triangle Institute (Research Triangle Park, NC) by high performance liquid chromatography (HPLC). The HPLC system consisted of a Waters model 510 pump (Waters, Inc., Milford, MA), a Rheodyne model 7125 injector, a Supelcogel TPR-100 column ( $15 \times 0.46$  cm; Supelco, Inc., Bellefonte, PA), and a  $\beta$ -Ram radioactivity detector equipped with a 100- $\mu$ L solid glass scintillator flow cell. The mobile phase was acetonitrile at a flow rate of 0.75 mL/minute (Method 1).

The chromatographic resolution of [ $^{14}$ C]-diisopropylcarbodiimide and [ $^{14}$ C]-diisopropylurea, a known metabolite of diisopropylcarbodiimide, was achieved with an HPLC system using an Alltech Alltima<sup>TM</sup> cyano column (250 × 4.6 mm ID, 5  $\mu$ m, 100 D; Alltech, Deerfield, IL) and a mobile phase consisting of hexanes:ethanol (95:5, v:v) at a flow rate of 0.75 mL/minute (Method 2). This method was used to determine the radiochemical purity of [ $^{14}$ C]-diisopropylcarbodiimide. Unlabeled 1,3-diisopropylurea was prepared from diisopropylcarbodiimide by acid hydrolysis. Approximately 2 mL of diisopropylcarbodiimide was mixed with approximately 20 mL of 0.1 M HCl. A white precipitate formed almost immediately. The mixture was filtered, and the solid diisopropylurea precipitate was rinsed with distilled water. The diisopropylurea was dried and then analyzed by GC/MS and NMR to confirm its identity.

To determine the stability of diisopropylcarbodiimide in whole blood from rats, a solution of [14C]-diisopropylcarbodiimide in propylene glycol was added to 1-mL samples of blood at 37° C. After mixing and incubating for approximately 1, 5, 10, or 30 minutes, 1 mL of hexanes was added to each sample. The samples were vortexed and centrifuged for 12 minutes at approximately 1,500 × g. Weighed aliquots of the hexanes extracts and pellets (after solubilization) were analyzed by liquid scintillation spectrometry and the total radioactivity extracted from blood was calculated. The extracts were then analyzed by HPLC using Method 2.

The concentration of <sup>14</sup>C in each dose formulation was determined prior to, during, and after dosing the animals. The radiochemical purity of each dose formulation was determined on the day of dosing by analysis of discrete fractions of HPLC column effluent using liquid scintillation counting (LSC).

The dose administered to each animal was based on its body weight on the day of dosing. Dermal dose formulations for rats and mice contained sufficient quantities of radiolabeled and nonradiolabeled diisopropylcarbodiimide (as appropriate) dissolved in hexanes to deliver doses of 4 to 41 mg/kg (approximately 0.07 to 0.9 mg/cm<sup>2</sup>) to rats, and 7 to 82 mg/kg (approximately 0.06 to 0.8 mg/cm<sup>2</sup>) to mice.

After use of the dosing apparatus, the needle was wiped with a Kimwipe® and the empty dosing apparatus was reweighed. The needle wipe was analyzed by LSC. The dermal dose per rat or mouse (in  $\mu$ Ci) was calculated as the difference in the weight of the syringe/needle dosing apparatus filled ( $S_R$ ) and empty ( $S_A$ ) multiplied by the

concentration of <sup>14</sup>C in the dosing formulation (A<sub>D</sub>) minus the <sup>14</sup>C contained in the needle wipe after dosing (NW) as shown:

$$\mu \text{Ci/rat or mouse} = (S_{\text{B}} - S_{\text{A}}) A_{\text{D}} - \text{NW}$$

Intravenous dose formulations for mice contained sufficient quantities of radiolabeled and nonradiolabeled diisopropylcarbodiimide (as appropriate) dissolved in propylene glycol to deliver a dose of approximately 8 mg/kg to mice in a dose volume of 1.3 mL/kg. The dose formulation was prepared on the day of dose administration and administered into one of the lateral tail veins. The intravenous dose (in  $\mu$ Ci) was calculated using the formula described above for the dermal studies in rats and mice.

In order to determine the efficiency of recovery from the charcoal filter, a solution of [ $^{14}$ C]-diisopropylcarbodiimide in hexanes (approximately 25  $\mu$ L), equivalent to a dermal dose formulation, was applied directly onto three pieces of charcoal-impregnated filter similar in size to the appliance covers used for the dermal experiments in mice. After approximately 20 minutes, each filter was cut into four pieces, oxidized, and analyzed by LSC.

In order to estimate efficiency of collection of [¹⁴C]-diisopropylcarbodiimide above the dermal application site, a volatilization experiment was conducted using a charcoal-impregnated filter as the primary trapping medium. A solution of [¹⁴C]-diisopropylcarbodiimide in hexanes (approximately 50 μL) was applied to the internal base of a 20-mL glass scintillation vial (Vial A) fitted with a Teflon<sup>®</sup> septum cap. Vial A was purged continuously with nitrogen through the septum, and the base of the scintillation vial was heated in a dry-bath incubator at approximately 32° C. The outlet tube of Vial A was packed with charcoal-impregnated filter material that led to another scintillation vial (Vial B) also fitted with a Teflon<sup>®</sup> septum cap. Vial B contained a solution of 0.1 M HCl (approximately 3 mL) and was vented into an exhaust hood. The charcoal-impregnated filter material was oxidized using a Packard Model 306C oxidizer (Perkin Elmer Life Sciences, Inc., Meriden, CT). ¹⁴CO₂ was trapped using Carbo-sorb<sup>®</sup> and analyzed by LSC using Permafluor<sup>®</sup> (Perkin Elmer Life Sciences, Inc.) as a scintillant. Samples, including the contents of Vials A and B, were assayed directly for total radioactivity by liquid scintillation counting.

Urine and feces were collected separately into containers cooled with dry ice. Urine was collected in this manner at 8, 24, 48, and 72 hours for the excretion studies. The urine collection containers were rinsed with methanol and then water at 8, 24, and 48 hours. The methanol rinses were analyzed separately. At sacrifice, urine was collected directly from the bladder and added to the 72-hour urine collection. Feces were collected at 24, 48, and 72 hours. Urine and feces collections were stored in the dark at approximately  $-20^{\circ}$  C until analyzed. After the animals were removed from the cages for sacrifice, the cages were rinsed well with water. An additional cage rinse using hexanes was also performed in an effort to recover volatilized radiolabel. All rinses were analyzed for radioactivity.

Radiolabeled volatile organics and  $^{14}\text{CO}_2$  were collected by passing air through the metabolism chamber (flow=approximately 200 to 550 mL/minute) through two cold traps, each containing approximately 60 mL of ethanol and then through a series of two traps, each containing approximately 500 mL of 1 N NaOH. The first cold trap was maintained at approximately 4° C using a water/ice bath, the second maintained at approximately  $-60^{\circ}$  C using an isopropanol/dry ice bath. For the studies, the traps were analyzed at 0 hours and analyzed and changed at 8, 24, 48, and 72 hours postdosing. The radiolabeled volatile organics were also collected by passing air from the metabolism chamber through a charcoal sorbent tube. The charcoal trap was located between the cryogenic and  $^{14}\text{CO}_2$  traps and was changed with the other traps at 4, 8, 24, 48, and 72 hours.

A skin wash procedure was performed after 6 hours of dermal exposure to [14C]-diisopropylcarbodiimide. The rats were anesthetized and the metal protective shield was removed and swiped for radioactivity. The charcoal filter was removed from the dose site, cut into approximately 20 to 25 pieces for rats and 10 to 12 pieces for mice,

placed into Combustocones<sup>®</sup> (Perkin Elmer Life Sciences, Inc.) in scintillation vials, and rapidly oxidized. For all the above-mentioned studies, the dose site, still attached to the animal, was thoroughly washed with gauzes soaked with hexanes, soapy water, and water. The gauzes and oxidized charcoal filters were analyzed by LSC. Afterwards, clean gauze was placed over the dose application site and wrapped with an Elastoplast<sup>®</sup> adhesive bandage for the duration of the study. At the termination of the dermal study in rats, animals were anesthetized and the Elastoplast<sup>®</sup> adhesive bandage was removed from the skin and extracted with acetone. The skin gauze was cut into approximately 8 to 10 pieces and divided into separate 20-mL scintillation vials each containing 2 mL of ethanol. The dose site was then removed by blunt dissection, and care was taken not to remove any muscle or adipose from under the skin. The excised skin was placed into a Nalgene<sup>®</sup> bottle containing approximately 75 mL of 2 N ethanolic NaOH.

At the termination of the 72-hour study, each animal was anesthetized, and its metal appliance shield was removed and stored in a plastic bag. The polyester/cotton fabric cover was removed from the foam appliance and placed into an amber bottle along with the Elastoplast® adhesive bandage and both were stored at approximately –20° C. The charcoal filter was removed from the appliance, cut into ten pieces, placed into Combustocones® in scintillation vials, and stored at approximately –20° C until oxidized. The appliance was then removed and cut into 8 pieces and divided into separate 20-mL scintillation vials each containing approximately 2 mL of ethanol. The dose application site and surrounding skin were carefully excised by blunt dissection. Care was taken not to remove any muscle or adipose from under the skin. The excised skin was attached to a glass and rinsed well with hexanes and the rinse collected. The dose site was then thoroughly washed with gauzes soaked with either hexanes or soapy water and the rinses were separately collected. The washed skin was placed into a Nalgene bottle containing approximately 75 mL of 2 N ethanolic NaOH. The rinses, dose application site wash gauzes, and the appliance pieces were analyzed by LSC.

Blood collections (approximately 300  $\mu$ L) were taken in some studies at 0, 0.02, 0.07, 0.13, 0.33, 1, 2, 8, 24, and 48 hours postdosing. Blood samples were collected into heparinized, disposable 1-mL glass syringes (GlasPak<sup>TM</sup>, Becton Dickinson & Co, Franklin Lakes, NJ). For tissue distribution studies, kidney, liver, lung, spleen, heart, testes, bladder, brain, and samples of adipose, muscle, and skin were excised from the animals and assayed for radioactivity. Carcasses were digested in 2 N ethanolic NaOH (500 mL for rats and approximately 75 mL for mice).

All samples collected during the studies were assayed for total radioactivity either directly (after dissolution in scintillation cocktail) or following digestion in an organic tissue solubilizer or 2 N ethanolic NaOH. Darkened samples were neutralized and bleached (using organic perchloric acid/hydrogen peroxide) prior to LSC. After addition of the scintillation cocktail, samples containing bases were allowed to sit in the dark for approximately 6 hours to minimize nonspecific chemiluminescence before being assayed. All samples were assayed for <sup>14</sup>C in a Packard liquid scintillation counter (Perkin Elmer Life Sciences, Inc.). The scintillation spectrometer was checked monthly for counting efficiency and was calibrated for quench correction using the external standard method. Approximately 12 mL of scintillation cocktail were added to duplicate aliquots of urine (approximately 0.1 to 0.6 g), methanol rinse (approximately 0.1 to 0.6 g), cage rinse (approximately 0.4 to 2.0 g) and hexanes cage rinse (approximately 0.5 to 1.0 g). Approximately 12 mL of scintillation cocktail were added to scintillation vials containing the samples of skin wash gauze and skin gauze cover. The samples were analyzed directly for total radioactivity. Duplicate aliquots (approximately 0.1 g) of the skin wash and hexanes skin rinse were also analyzed for radioactivity. Approximately 12 mL of scintillation cocktail was added to scintillation vials containing the rinse aliquots.

Duplicate aliquots (0.5 to 2.0 g) of the breath trap contents were weighed into scintillation vials containing approximately 12 mL of scintillation cocktail and samples were assayed for total radioactivity. Duplicate aliquots of the charcoal tube contents were oxidized and assayed for total radioactivity. Feces were homogenized with an approximately equal mass of water. The weight of the feces homogenate was determined, and weighed aliquots (0.05 to 0.2 g) were solubilized in 2 mL of Soluene®-350 (Perkin Elmer Life Sciences, Inc.). After digestion,

approximately 12 mL of scintillation cocktail were added and the samples were analyzed for total radioactivity. Duplicate aliquots (approximately 0.05 g) of blood were weighed into scintillation vials containing 2 mL of Soluene®-350. The samples were neutralized and decolorized by treatment with perchloric acid/hydrogen peroxide and assayed for radioactivity. Tissue samples (approximately 0.01 to 0.9 g) were digested in 2 mL of Soluene®-350 using a mechanical shaker. Small tissues and organs, and aliquots of large tissues (i.e., skin, adipose) were analyzed in their entirety. For rats, if large organs (i.e., liver) were homogenized, weighed aliquots of the homogenate were analyzed. Colored tissues were neutralized and decolorized with perchloric acid/hydrogen peroxide, and assayed for radioactivity. Residual radioactivity present in the carcass and dose application site was recovered by digesting the tissues in 2 N ethanolic sodium hydroxide. To hasten digestion, the carcass and dose application site collections were shaken for approximately 96 hours. After complete digestion, aliquots (approximately 0.2 to 0.7 g) were analyzed for total radioactivity. The amount of radiolabel reported for the residual carcass was calculated by subtracting the measured amounts of radiolabel in the large tissues (adipose, muscle, skin, and blood) from the measured amount in the total carcass digest.

#### RESULTS

With baseline resolution, the radiochemical purity of [¹⁴C]-diisopropylcarbodiimide was found to be approximately 94%, with an impurity of approximately 3% detected at the retention time for [¹⁴C]-diisopropylurea. The identity of a synthetic standard of 1,3-diisopropylurea was confirmed by both mass spectrometry and ¹[H]-NMR spectroscopy.

When rat blood was spiked with [¹⁴C]-diisopropylcarbodiimide in propylene glycol and extracted almost immediately, approximately 70% of the radiolabel was extracted by hexanes. Following 30 minutes of incubation, only approximately 15% of the radiolabeled dose was extracted. When the hexanes extracts were analyzed by HPLC, approximately 90% of the radiolabel extracted after incubation for up to 10 minutes was [¹⁴C]-diisopropylcarbodiimide. By 30 minutes, only 73% of the extracted radiolabel (which represented approximately 15% of the total radiolabel) eluted as [¹⁴C]-diisopropylcarbodiimide.

Charcoal-impregnated cellulose filters retained approximately 90.6% of the applied radioactivity after 20 minutes of storage at room temperature. When the experiment was repeated with additional time points and storage of the filters in sealed scintillation vials, the charcoal-impregnated filters retained approximately 97.6%, 96.4%, 97.3%, 95.5%, and 95.9%, respectively, of the applied radioactivity when analyzed 0, 3, 24, 48, and 72 hours after dosing.

#### **Dermal Studies**

#### Rats

As shown in Tables L1 and L2, approximately 1.4% and 0.5% of the administered radioactivity was excreted in urine for Study A1 (4.1 mg/kg) and Study A2 (3.9 mg/kg), respectively, and less than 0.2% was excreted in feces through 72 hours following dose application for both studies. Less than 2% of the radioactivity was measured as volatile organics or  $^{14}\text{CO}_2$  for Study A1, while approximately 0.5% of the dose was measured as volatile organics for Study A2. For Study B, a minimal fraction of the 40.9 mg/kg dose (approximately 1% of the total) was excreted in urine, feces, and breath over the same time interval (Table L3).

As shown in Table L4, total dermal absorption of the radiolabeled doses was approximately 7% and 2% for Studies A1 and A2, respectively. Approximately 1% and 0.6% of the radiolabeled doses remained in the dose application site skin for studies A1 and A2, respectively. Less than 0.5% was found in the residual carcass for both studies. For Study B, approximately 0.1% of the radiolabeled dose remained in the dose application site skin as well as in the carcass; total dermal absorption of the radiolabeled dose was approximately 1%.

In Study A1, the average total recovery of the radiolabeled dose was approximately 72%, and included approximately 65% of the dose that was unabsorbed. When this study was repeated (Study A2), the average total

recovery was approximately 86% and included approximately 84% of the dose that was unabsorbed. For Study B, the average total recovery was approximately 97% of the radiolabeled dose, and included approximately 96% of the dose that was unabsorbed.

Table L5 shows the concentration of diisopropylcarbodiimide-derived radiolabeled material in the tissues 72 hours following each dermal exposure. For each study, only a negligible percentage of the dose was found in the assayed tissues and the residual carcass. None of the tissues collected for Study A1 were found to have appreciable tissue:blood ratios (values >10). For Studies A2 and B, the tissue:blood ratios could not be determined since the calculated disintegrations per minute for blood were not significantly different from background samples.

#### Mice

In Study E, mice received an average dermal dose of 6.9 mg/kg (approximately 0.06 mg/cm² and approximately  $26.6 \,\mu$ Ci/animal). During the exposure, the dose application site was protected by a charcoal-covered wire tissue capsule appliance that was put in place after the dose was applied. Approximately 0.7% of the administered radioactivity was excreted in the urine, and approximately 0.4% was excreted in the feces through 72 hours following dose application (Table L6). Less than 1% of the radioactivity was trapped as volatile organics and  $^{14}\text{CO}_2$ . Results presented in Table L7 show that an average of only 6.5% of the administered dose was recovered in 72 hours following dose application. Less than 0.2% of the radiolabeled dose remained in the dose application site skin and the residual carcass. Approximately 2% of the dose was absorbed during the 72-hour exposure. Table L8 shows the concentrations of diisopropylcarbodiimide-derived radiolabel in the tissues 72 hours following dose application. Only a negligible percentage of the dose was found in the tissues and residual carcass; however, an elevated tissue:blood ratio (>10) was observed for skin.

#### **Intravenous Studies**

In Study G, mice received an average intravenous dose of 7.6 mg/kg (2.01  $\mu$ Ci/animal). As shown in Table L9, approximately 37% of the administered dose was excreted in urine, and approximately 11% was excreted in feces through 48 hours following dose administration. An average of 29% of the radioactivity was exhaled as  $^{14}$ CO<sub>2</sub>, and approximately 8% was exhaled as volatile organics. Approximately 84% of the radiolabeled dose was recovered after 48 hours.

Table L10 shows the concentrations of diisopropylcarbodiimide-derived radiolabel in the tissues 48 hours following dosing. Only a negligible percentage of the dose was found in selected tissues and the residual carcass. None of the assayed tissues were found to have appreciable tissue:blood ratios.

In Study H, mice received an average intravenous bolus dose of 7.8 mg/kg (1.02 µCi/animal). As shown in Table L11, 7.6% of the injected dose was measured in blood 1 minute after dosing. Considerable animal-to-animal variation was observed in the concentration of radioactivity in blood during the first hour. Thereafter, the average percent dose measured in blood steadily decreased to less than 0.3% of the injected dose at 48 hours after dosing.

#### **DISCUSSION**

The radiochemical purity of [¹⁴C]-diisopropylcarbodiimide was found to be sufficiently high (approximately 94% with an impurity of approximately 3%) to enable disposition studies. In earlier studies, sublimation of the test chemical complicated dermal studies with a similar carbodiimide, dicyclohexylcarbodiimide. Hence, an *in vitro* volatilization experiment was performed with [¹⁴C]-diisopropylcarbodiimide to determine whether volatilization would complicate dermal studies involving this test chemical as well. The *in vitro* experiment demonstrated that the use of a trapping material to recover volatized dose would be required for acceptable mass balance in dermal studies.

An experiment to test charcoal as a potential dermal appliance trap for volatilized [14C]-diisopropylcarbodiimide demonstrated that the volatilized radiolabel could be recovered from a charcoal-impregnated filter by combustion with subsequent analysis by LSC. This experiment was run for approximately 20 minutes without a freeze-thaw cycle for the samples, and did not address the continued stability of [14C]-diisopropylcarbodiimide-related compounds in charcoal beyond approximately 20 minutes. Subsequently, an experiment was conducted to determine the effect of a freeze-thaw cycle on the stability of diisopropylcarbodiimide-related compounds trapped on activated charcoal. This experiment confirmed that an acceptable percentage of radiolabeled doses could be recovered from a charcoal-impregnated filter by combustion with subsequent analysis by LSC if the samples were oxidized and analyzed within 72 hours of dose administration.

Blister-type appliances constructed form charcoal-impregnated cellulose were developed for use in recovering volatilized dermal doses of diisopropylcarbodiimide. Prior to use of the charcoal protective appliances in any inlife studies, the appliances were tested to determine the optimal dosing procedure that would ensure adequate recovery of radiolabeled doses, uniform dosing across the dose application site area, and minimal contamination of the appliance or surrounding skin with the applied dose.

Because the covering of the dose site was opaque, it was not possible to actually view the dose as it was being applied to the skin. To simulate the results of dose application, a mock dose formulation containing food coloring in ethanol was applied through the charcoal appliance using several techniques. After removal of the appliance, the food coloring aided in visualizing where the dose had accumulated. By use of specially constructed appliances that contained Teflon®-sheeted windows, actual dose administration was observed to verify delivery of the dose over the entire dose application area. In summary, these experiments led to the development of a nonocclusive dermal appliance that was subsequently used with success to improve recoveries of radiolabeled doses in mass balance studies involving [14C]-diisopropylcarbodiimide.

In addition to its volatility, [¹⁴C]-diisopropylcarbodiimide is also extremely reactive; it reacts rapidly in blood to form products that are not extracted by nonpolar organic solvents. In an *in vitro* experiment, after 30 minutes of incubation, only 15% of administered radiolabel was extracted from blood with hexanes. Of this 15%, approximately 73% was identified as diisopropylcarbodiimide by HPLC analysis. It was postulated that it was still possible to measure diisopropylcarbodiimide after 30 minutes only because of the small size of the blood sample; likely, the blood component(s) that reacted with diisopropylcarbodiimide was of limited supply. In systemic circulation, this would not be the case, so it would be unlikely that parent diisopropylcarbodiimide could be measured in blood in an in-life experiment.

Dermal studies were conducted in rats at doses of approximately 4 and 41 mg/kg to determine the dermal absorption of diisopropylcarbodiimide, the rates and routes of excretion, and the terminal body burden. The dose application site was protected by a foam appliance covered with a charcoal-impregnated filter to help trap volatilized diisopropylcarbodiimide. Diffusion of diisopropylcarbodiimide into the foam led to the conclusion that the appliance was not suitable for adequate recovery of the radiolabeled dose, and prompted the use of a nonocclusive blister-type charcoal-impregnated appliance. The high radiochemical dose and the volatility of diisopropylcarbodiimide led to high levels of radioactivity in the dose-site appliances. Due to these high levels of radiolabel, the appliances had to be reanalyzed. The low recovery of radiolabeled doses was most likely due to desorption of <sup>14</sup>C from the charcoal filter and possibly the foam appliance prior to analysis. Therefore, the exposure time was limited to 6 hours to minimize desorption time, and the charcoal appliances were combusted within a few hours of removal from the animals. These changes resulted in improved recovery of the radiolabeled doses. The average total recoveries were approximately 72%, 86%, and 97% of the radiolabeled doses and included approximately 65%, 84%, and 96% of the doses that were unabsorbed, respectively.

In rats, only small percentages of the radiolabeled doses were absorbed (approximately 6.6%, 1.9%, and 1.1%) and excreted (approximately 5.1%, 1.0%, and 1.0%). None of the assayed tissues were found to have substantially elevated tissue:blood ratios, and no target organs were identified. The majority of each dose appeared to have been

volatilized from the dose application site and was not available for absorption. The tissue:blood ratio could not be determined for two of the three dermal studies in rats because the measured radioactivity in blood was not significantly different from that of background.

A similar study was performed in mice at a dermal dose of 6.9 mg/kg, again to determine the dermal absorption of diisopropylcarbodiimide, the rates and routes of excretion, and the terminal body burden. During the study, the dose application site was not occluded, but was protected by a metal tissue capsule covered with a charcoal-impregnated filter to trap volatilized diisopropylcarbodiimide. The appliance was attached to the animal after the dose was applied. Only a small percentage of the radiolabeled dose was absorbed (approximately 2.3%) and excreted (approximately 2.2%) during the 72-hour study. Almost none of the dose remained in the dose application site skin or the residual carcass, including the selected tissues, suggesting that the applied dermal dose rapidly volatilized from the dose application site. The average total recovery was only approximately 7% of the radiolabeled dose and included approximately 4% of the dose that was unabsorbed. A possible explanation for the low recovery is that the dose volatilized from the dose application site prior to being covered with the charcoal-covered appliance.

Two dermal studies were conducted in mice with doses of approximately 80 mg/kg to determine the dermal absorption versus volatility of diisopropylcarbodiimide after a 6-hour exposure. For both studies, the dose application site was protected by a blister-type nonocclusive charcoal-impregnated appliance. The dose was administered through the appliance to minimize the volatilization loss of diisopropylcarbodiimide during dosing. An appliance with an outer diameter of 6 cm (ungathered) was attached to the backs of the mice prior to dosing. This appliance did not create a proper seal on the animal and resulted in a recovery of 82.5%. A smaller appliance was fashioned with an outer diameter of 5 cm, and the recovery was successfully increased to 91.2%. For these two dermal studies in mice, similar to the results from the dermal studies in rats, only small percentages of the radiolabeled doses were absorbed (approximately 0.1% and 0.5%, respectively) and excreted (approximately 0.02% and 0.01%, respectively). Once again, the majority of the dose was recovered in the charcoal-impregnated appliances. In the first study, approximately 82.4% of the dose was not absorbed, of which 82.3% was contained in the charcoal appliance; in the second study, approximately 90.7% of the dose was unabsorbed and 90.5% was contained in the appliance. The majority of the dose rapidly volatilized from the dose application site and was not available for absorption.

Following a 7.6 mg/kg intravenous dose to mice, approximately 37% of the administered dose was excreted in urine, and approximately 11% was excreted in feces within 48 hours after dosing. Approximately 29% of the radioactivity was exhaled as  $^{14}CO_2$ , and approximately 8% was exhaled as volatile organics. Only a small percentage of the dose was found in the analyzed tissues (approximately 7%) and the residual carcass (approximately 1.7%). None of the assayed tissues were found to have elevated tissue:blood ratios of radiolabel and approximately 84% of the radiolabeled dose was recovered after 48 hours.

An intravenous injection study was conducted in mice using a dose of 7.8 mg/kg to determine the time course of radioactivity in blood. At each time point, three to four animals were sacrificed and aliquots of blood were analyzed (serial blood sampling from the same animal was not possible). At 1 minute postdosing, only approximately 7.6% of the administered radiolabel was measured in circulatory blood. This was the highest measured percentage of any time point, but a steady trend did not follow. For the first hour, the animal-to-animal variation in the amount of circulating radiolabel was high. After 1 hour, the percentage of the dose measured in blood steadily decreased at each subsequent time point until less than 0.3% of the dose remained in blood at 48 hours after dosing. The amount of radiolabel recovered in blood suggests that diisopropylcarbodiimide may chemically react at or near the site of injection and not be entirely systemically available. In addition, the identity of the radiolabeled compounds measured in blood is uncertain. It is probable that the radioactivity is not associated with [14C]-diisopropylcarbodiimide, but rather radiolabeled metabolites or reaction products in blood. The formation of reaction products or metabolites may contribute to the variability observed during the first postdosing hour.

 $<sup>^{</sup>a}$  Data are presented as cumulative percentage of the dose (mean  $\pm$  standard deviation) for four mice.

Table L7 Distribution of Radioactivity in Male  $B6C3F_1$  Mice 6 or 72 Hours After a Single Dermal Application of [ $^{14}$ C]-Diisopropylcarbodiimide: Study  $E^a$ 

	$6.9 \text{ mg/kg}^{\text{b}}$	
Absorbed Dose		
Urine <sup>c</sup>	$0.7\pm0.4$	
Feces	$0.4 \pm 0.2$	
Exhaled CO <sub>2</sub>	$0.8 \pm 0.1$	
Volatile Organics Trapped by Ethanol	$0.3 \pm 0.1$	
Volatile Organics Trapped by Charcoal	$0.005 \pm 0.001$	
Application Site Skin	$0.13 \pm 0.03$	
Residual Carcass <sup>d</sup>	$0.01 \pm 0.01$	
Collected Tissues	$0.014 \pm 0.001$	
Total Absorbed Dose	$2.3\pm0.4$	
Unabsorbed Dose		
Charcoal Cover	$1.7 \pm 0.5$	
Skin Wash	$0.8 \pm 0.5$	
Appliance/Elastoplast® Extract	$1.6 \pm 0.3$	
Instrument Swipe	$0.01 \pm 0.01$	
Hexanes Cage Rinse	$0.01\pm0.00$	
Total Unabsorbed Dose	$4.1\pm0.6$	
Total Dose Recovered	$6.5\pm0.6$	

NA=Not applicable. Value was not significantly different from background and the absorbed dose could not be calculated.

b Included methanol rinse at 8, 24, and 48 hours; cage rinse included at 72 hours

No collection was scheduled for this time interval

<sup>&</sup>lt;sup>a</sup> Data are presented as percentages

b Data are presented as mean  $\pm$  standard deviation for four mice; study duration was 72 hours

<sup>&</sup>lt;sup>c</sup> Urine included cage rinse and methanol rinse.

d Dose recovered in the residual carcass less the dose measured in skin, muscle, adipose, and blood.
